...the new honestly priced Liquid Scintillation and Automatic Gamma Counters from Philips...

...the end to price confusion.

Just how important is price?

Of course price is important. But not price at any price.

Price not as a result of your ability to beat the salesman down. With Philips you won't have to argue about price.

The Philips price is realistic. Our price is based on the value of our products.

No more – no less.

The new Philips Liquid Scintillation and Automatic Gamma Counters.

The new generation for the eighties.

In styling and performance.

In our price the availability of service is included.
For at least 10 years.

In our price the availability of spare parts is guaranteed.
For at least 10 years.

Compare Philips with others in this field.
For price and performance.

We invite your comparison.
To find out the facts fill in the coupon, or write, telephone or telex, but whatever you do, contact us.

Please send me detailed information on:

○ Philips Liquid Scintillation Counter.

○ Philips Automatic Gamma Counter.

FROM THE MACMILLAN PRESS

New Titles

THE ECOLOGY AND CONSERVATION OF LARGE AFRICAN MAMMALS
S. K. Eltringham, with a foreword by Sir Peter Scott CBE DSC
"The flora and fauna of Africa are one of the greatest wonders of the world. Mankind has a responsibility to assure their continued existence and I believe this book will significantly help to do just that." *Sir Peter Scott*
A scholarly but readable account, summarising the findings of the many wildlife research stations at work in Africa.
£15.00 0 333 23580

EVOLUTIONARY ECOLOGY
Bernard Stonehouse and Christopher Perrins
Available for the first time in paperback
"This is a book which every keen amateur naturalist should read." *Oxford Mail.*
21 essays in honour of Dr. David Lack. They cover four main areas; Population regulation and Function of territory, Feeding adaptions and Ecological segregation, Breeding adaptions and Reproductive rates, and Behaviour, Adaption and Taxonomic relationships.
£5.95 0 333 281626

DECISION MAKING FOR ENERGY FUTURES: A case study of the Windscale inquiry.
D. W. Pearce et al.
Who decides the Scientists and Technicians or the Politicians?
Using the application by BNFL to set up an oxide fuel reprocessing plant at Windscale the authors of this study examine the ways in which our energy future is being decided.
The come to some controversial conclusions. They believe that national issues are being removed from democratic control as a result of their deliberation outside parliament and within the bureaucratic planning machinery.
£10.00 0 333 274385

A DICTIONARY OF THE ENVIRONMENT
Michael Allaby
Now in PAPERMAC
DEFINES SOME 6,000 WORDS AND PHRASES.
"The rapidly evolving vocabulary of any one of the life or earth sciences ... can be bewildering both to the lay reader and the specialist trained in another field. Michael Allaby's *A Dictonary of the Environment* attempts to cover them all, and to appeal to lay reader and scientists alike." *Richard Clarke-Nature*
£3.95 0 333 274490

To be published in February 1980

GROWTH WITHOUT ECODISASTERS
N. Polunin
The environment is under attack. Its resources have been plundered to sustain industrial and technological growth. If growth is to continue and man is to live in a pleasant and healthy environment its use must be carefully planned and controlled.
The 18 chapters in this book are based on the keynote papers, and the discussions that followed them, presented at the 2nd International Conference on Environment Future held at Reyjavik in 1977. Papers, each of which was presented by a specialist in the field, range from Fresh waters and their biota to Life-style alternatives and the Ethics of biospheral survival.
£17.00 0 333 235515

THE CHAIN STRAIGHTENERS: FRUITFUL INNOVATION – THE DISCOVERY OF LINEAR AND STEREO-REGULAR POLYMERS
Frank M McMillan
The story of the remarkable burst of scientific discovery and technological innovation that gave science mastery over the 3-dimensional structure of high polymers and the world its most useful group of plastics and synthetic rubbers. A story surrounded by controversy, where science meets big business and powerful personalities clash. This will undermine many of the conventional views of scientific innovation.
£9.00 0 333 259297

FROM DNA TO PROTEIN: The Transfer of Genetic Information
Maria Szekely
This is the first textbook which discusses gene structure on the basis of recent discoveries of overlapping and split genes and which gives a consistent image of the ways in which genetic information can be encoded into the genetic material and how it can be transfered to other materials.
A perfectly up-to-date account of our present knowledge of the structure and expression of genes in prokaryotic and eukaryotic organisms and the only available text showing the correlation between the structure and function of nucleic acids.

The Zoology of

THE VOYAGE OF
H.M.S. BEAGLE

CHARLES DARWIN

Available for the first time — a 3 volume facsimile reprint of this important and rare work

SPECIFICATIONS
Size: 318mm x 250mm (12½" x 9¾")
Extent: 1008 pages (3 volumes)
Plates: 165 (83 B/W, 82 colour)
Binding: ¼ bound in leather with quality linen
Edition strictly limited to 750 copies
Price £309.00

Over 500 species of fossil mammals, mammals, birds, fish and reptiles are described and illustrated by the best authorities of the time, supervised and edited by Charles Darwin.

Among the numerous illustrations are 50 colourplates of birds by John Gould.

New books from **CAMBRIDGE**

Plant Hormones and Plant Development

WILLIAM P. JACOBS

This textbook describes various aspects of plant development and how plant hormones circulate through plants and control and coordinate development. Professor Jacobs traces the historical evolution of our current understanding of plant development and emphasises the development of research techniques and ideas. He also points out the importance of proper assessment of evidence, by discussing how the uncritical use of new techniques has interfered with progress in the field. This textbook will be invaluable to students of plant physiology, biochemistry and agriculture and to professional workers concerned with plant development.

Hard covers £18.00 net
Paperback £5.95 net

Fungal Walls and Hyphal Growth

Edited by J. H. BURNETT and A. P. J. TRINCI

This volume both reviews recent work on all aspects of the cytology, physiology and biochemistry of fungal walls and hyphal growth and includes original contributions from a number of distinguished research workers. Many of the articles concentrate on detailed investigations of a number of well-known fungi, but current ideas of wider application are also dealt with. The book will be invaluable to students and research workers in mycology and to those interested in experimental morphogenesis.

British Mycological Society Symposium 2 **£27.50 net**

Estuarine Hydrography and Sedimentation

Edited by KEITH R. DYER

This handbook discusses methods for studying estuarine hydrography and sedimentation, with particular emphasis on the advantages and disadvantages of each method. The topics covered include tidal measurements, echo-sounding, oblique asdic and seismic profiling, bed sediment and suspended sediment sampling and analysis, and the measurement of water velocity, salinity and temperature. The information provided can be applied to estuarine regions all over the world and should benefit students and research workers in environmental science, physical oceanography, and marine chemistry, biology and geology, as well as hydrographic surveyors.

Buoyancy Effects in Fluids

J. S. TURNER

In this monograph the author gives an account of the various motions which can be driven or influenced by buoyancy forces in a stratified fluid. The emphasis throughout is on providing a clear physical understanding of the processes described, making this a useful text for meteorologists, oceanographers and engineers.

'. . . a welcome addition to the list; the content is good, the typeface and editing are a delight, and there is a superb collection of photographs and figures.' *American Scientist*

Paperback £7.95 net

Still available in hard covers

Physical and Mechanistic Organic Chemistry

R. A. Y. JONES

This textbook seeks to enable the reader to understand the general principles on which the study of reaction mechanisms is based and to apply them to most reactions in organic chemistry. The first part of the book describes the techniques available for probing reaction mechanisms while the second part examines the application of these methods to some of the more important classes of reactions. This book will be welcomed by students of organic chemistry and professional chemists.

Paperback edition

A Handbook of Numerical and Statistical Techniques

With Examples Mainly from the Life Sciences

J. H. POLLARD

'When books on basic statistics continue to appear with amazing regularity, it is refreshing to find one which more than permutes the 'usual material'. This book not only describes essential statistical techniques but gives a welcome priority to elementary numerical methods . . . its uniformity and clarity of presentation, together with its comprehensiveness, should give it wide appeal . . . It should be a valuable asset to the scientist and statistician.' *Nature*

Paperback £5.50 net

GUIDE TO AUTHORS

- Review articles should be aimed at a relatively wide readership. Many reviews are invited, but submitted articles may also be accepted; it is advisable to consult us before writing a review article.
- Articles may be up to 3,000 words long with at most six displayed items (figures and tables); they are reports of major research developments.
- Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words; they have at most three or four displayed items.
- 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*.

Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusion in terms intelligible to as wide a readership as possible.

Manuscripts may be submitted either to London or New York. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should be identified in the margin on their first appearance. Equations should occupy single lines if possible: exp (a) is preferred to e^a if 'a' is more than one character.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) only one reference number need be used if the reference is to several papers by identical authors.

(ii) first and last pages of references should be cited.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth edn (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated 'Personal communication' and 'unpublished' should be incorporated in text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. Ideally, an unaltered original and three lettered copies should be provided; labelling on halftones should, if possible, be avoided entirely. Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Nature's publishing policy is outlined in **258**, 1 (1975) and **264**, v, 11 Nov. (1976).

HORMONAL CONTROL OF EPITHELIAL TRANSPORT

Edited by J. BOURGUET, J. CHEVALIER, M. PARISI, P. RIPOCHE
INSERM Vol. 85 — 420 pages/70FF/18 US dollars including air mail postage
37 papers in English

Proceedings of the INSERM SYMPOSIUM held in Paris, May 1979, dealing with the following topics:

- **CULTURAL TECHNIQUES IN THE STUDY OF EPITHELIAL TRANSPORTS**
- **STEPS IN HORMONE ACTION**
- **MECHANISM OF ACTION OF ALDOSTERONE**
- **MORPHO-FUNCTIONAL CORRELATIONS**
- **IONIC TRANSPORTS**
- **WATER MOVEMENTS**
- **OTHER ASPECTS OF EPITHELIAL TRANSPORT**

Chairman: I. L. Schwartz *(New York, USA)*; J. Crabbé *(Brussels, Belgium)*; B. Lindeman *(Hombourg, Germany)*; J. Schlessinger *(Rehovot, Israel)* E. Skadhauge *(Copenhagen, Denmark)*; A. Cuthbert *(Cambridge, England)*; R. de Sousa *(Geneva, Switzerland)*; A. Taylor *(New York, USA)*.

At Last! A Reliable Incubator Under $100

Designed for Aerobic or Anaerobic Tissue Culture Experiments

Shown at ASM and FASEB Meetings

With this Modular Incubator Chamber you no longer have to worry about the inherent variability (due to CO_2, temperature and humidity fluctuations) of present day continuous flow and anaerobic incubators.

Simply place your experiment into the sealed chamber, purge the system with the required gas mixture and set in a controlled temperature environment.

Because each chamber is an isolated system you now have the flexibility to design experiments you previously thought were impractical or too expensive.

Chamber and tray components are made from rugged, non-toxic, uv-resistant polycarbonate.

Multi-purpose trays conveniently hold petri dishes, test tubes, T.C. flasks, microtest plates, etc.

Chambers can be stacked and interlocked for agitation or storage.

And now for the best part. The price of the chamber with 3 trays is only $95.* To order or for further information phone or write Billups-Rothenberg, Inc., Dept. N-1, P.O. Box 977, Del Mar, CA 92014 USA (714) 755-3309.

Spiders

E.O. Wilson: Let me remind you that people everywhere, a large percent of the population, at a very early age have already developed a deep horror at the sight of snakes or spiders with nothing more than gentle nudging from their parents, if that. Yet, in spite of the fact that parents constantly reinforce their children against going near electric sockets, automobiles, knives and the like, phobias against such objects rarely develop.

Marvin Harris: Let's go back again to the possibility that these phobias are genetically programmed – which I'm willing to grant. The overwhelming bulk of the socially conditioned response repertories of different human societies consists, by your own admission, of culturally determined rather than genetically determined traits. Then it seems to me that when one offers a cogent culturological explanation of th

has to be considered tha

offered in

ces of human

ch gigantic phenomena as the

gence of state-organized societies or the emergence of stratified classes and castes. The enormous differences between industrial civilization and pre-industrial societies, peasant or village ways of life

... from a debate between E.O. Wilson and Marvin Harris on sociobiology. In The Sciences. From family constellations to galaxies, The Sciences takes the critical look. Handsome, original, lively, The Sciences represents the best science commentary you'll find anywhere on human behavior, culture, the physical sciences — by Ashley Montagu, Stephen Jay Gould, B.F. Skinner, Napoleon Chagnon, Peter Medawar

Raven Press

VIRAL ONCOLOGY

Edited by George Klein

This exciting volume, edited by one of the world's foremost authorities, is the first comprehensive source book and guide to the field for virologists, cell biologists, oncologists, and geneticists. Chapters discuss tumor viruses for RNA (avian, murine, and primate oncornaviruses) and DNA (papovaviruses, adenoviruses, and herpesviruses). **Approximately 875 pages, 7 x 10 inches, tentatively $115.60 (1980)**

ORGANELLE HEREDITY

Nicholas W. Gillham

"The most thorough treatment yet of mitochondrial and plastid genetics, and deserves to be read widely by geneticists, biochemists, cell biologists, and advanced students. . . .A milestone in the history of genetics."—Nature

"Likely to be the standard reference for many years."—Science

618 pages, 7 x 10 inches, $67.32

ADVANCES IN PROSTAGLANDIN AND THROMBOXANE RESEARCH VOLUMES 6-7-8

Fourth International Prostaglandin Conference, Washington, D. C.

Edited by Bengt Samuelsson, P. Ramwell, and Rodolfo Paoletti

Areas covered include biochemistry, pharmacology, cardiology, trauma, hematology, endocrinology, renal function, reproduction, gastroenterology, inflammation, pulmonary function, neurology, neuroscience, growth and development of tissues, nutrition, and current laboratory and clinical research methods. **3 volume set: 2000 pages, $217.60; individual volumes, $74.80 (1980)**

ADVANCES IN INFLAMMATION RESEARCH, VOLUME 1

Edited by Gerald Weissmann, Bengt Samuelsson, and Rodolfo Paoletti

SECTION HEADS: Membranes and Blood Vessels / Inflammatory Cells / Circulating and Local Mediators of Inflammation / Immune Mechanisms of Inflammation / Arachidonic Acid-Derived Mediators of Inflammation / Anti-inflammatory Drugs and Pharmacological Studies / Clinical Studies / Subject Index. **666 pages, $67.32 (1979)**

PROSTACYCLIN

Edited by John R. Vane and Sune Bergström

This volume is a comprehensive review of our current understanding of the chemistry, physiology, and pharmacology of prostacyclin and its analogs. It should be of interest to cardiologists, pharmacologists, physiologists, biochemists, and clinical researchers. **466 pages, $53.72 (1979)**

TRACER KINETIC METHODS IN MEDICAL PHYSIOLOGY

Niels A. Lassen and William Perl

This book provides a concise introduction to the mathematical treatment of tracers as used in medical and physiological research. Methods for measuring blood volume, cardiac output, cerebral circulation, plasma albumin metabolism, red cell production, and capillary permeability are presented. **199 pages, $32.64 (1979)**

BIOLOGICAL BASIS OF IMMUNODEFICIENCY

Edited by Erwin W. Gelfand and Hans-Michael Dosch

This volume provides a multidisciplinary approach to the study of the immune system and immunodeficiency diseases, and will interest immunologists and pediatricians involved in the diagnosis and management of such conditions. **362 pages, $44.88 (1980)**

AGING, IMMUNITY AND ARTHRITIC DISEASES

Aging, Volume 11

Edited by Marguerite M. B. Kay, Jeffrey E. Galpin, and Takashi Makinodan

Using an immunologic approach to arthritic diseases of the aged, this volume reviews the biology, immunology, and cell biology necessary for understanding their underlying pathogenesis, and presents the most fruitful ongoing research and possible clinical applications. **Approximately 200 pages, tentatively $29.92 (1980)**

MEMBRANE-MEMBRANE INTERACTIONS

Society of General Physiologists, Volume 34

Edited by Norton B. Gilula

This volume examines the various molecular mechanisms involved in generating and maintaining interactions between membranes in a variety of biological systems. SECTION HEADS: Membrane and Model Systems / Short-Term or Transient Interactions / Long-Term or Stable Interactions / Subject Index. **Approximately 245 pages, tentatively $36.72 (1980)**

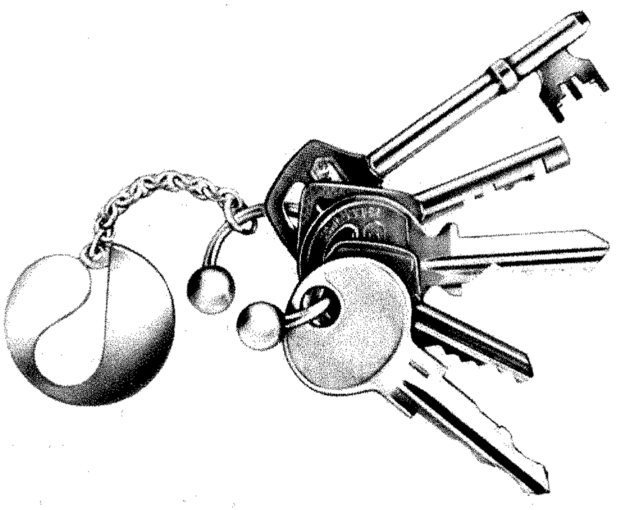
Affinity chromatography – your keys to success!



- high selectivity and low non-specific adsorption for pure product
- ready-to-use for greater time-saving
- porous matrix for high capacity, concentrated product
- excellent flow properties for fast results
- reusable for economical separations

Group specific adsorbents for the key step in your purification

Protein A-Sepharose CL-4B	IgG, antigens, immune complexes
Con A-Sepharose	glycoproteins, glycolipids, polysaccharides
Lentil Lectin-Sepharose 4B	membrane glycoproteins
Heparin-Sepharose CL-6B	plasma proteins, enzymes etc
Poly(U)-Sepharose 4B	mRNA, plant nucleic acids
Poly(A)-Sepharose 4B	mRNA-binding proteins, hnRNA
Lysine-Sepharose 4B	plasminogen, ribosomal RNA
Blue Sepharose CL-6B	serum albumin, nucleotide-requiring enzymes
5'AMP-Sepharose 4B	NAD^+-dependent dehydrogenases
2'5'ADP-Sepharose 4B	$NADP^+$-dependent dehydrogenases

EMBO
Laboratory Course
"Bacterial Genetics"

Cologne, FRG, September 8-27, 1980
Institute of Genetics,
University of Cologne

The course is intended to practice methods using transposable DNA elements both in E.coli and other gram-negative bacteria. Emphasis is strongly on genetics, rather than on the biochemical techniques used in this type of work because we think that the latter techniques are more widely known. Participants will have the opportunity however to familiarize themselves with biochemical techniques in the Institute of Genetics, if they desire.

The experiments offered and the teaching staff are listed below. Participants interested in pursuing a project of their own along these lines (e.g. use of particular bacterial strains) are invited to discuss this with the organizers four weeks in advance.

List of Experiments:

1. *Mutagenesis of E.coli K12 by cI857::Tn9 and cI857::Tn10 (or possibly Tn5 instead of Tn10)*
2. *Isolation and characterization of Gal-mutants caused by the insertion of a transposon*
3. *Integration of a transposon between att and gal, isolation of dgal phages carrying the transposon*
4. *Determination of the influence of host mutations on transposition, precise excision and adjacent formation with IS elements*
5. *Isolation of mutants effecting illegitimate recombination*
6. *Characterization of plasmids carrying deletions adjacent to an IS element (isolation of large plasmids, restriction analysis)*
7. *Chromosome mobilisation in E.coli and Pseudomonas aeruginosa by R 68.45*
8. *Genetic marking of large plasmids by transposons (e.g. Ti-plasmids of Agrobacterium)*
9. *Use of suicide vectors in interspecific crosses*
10. *Mobilization of E.coli genes by bacteriophage mu*
11. *Test of Erwinia strains for unknown conjugative plasmids*
12. *Plasmid-mediated specific adhesion of bacteria to animal cells (including a monitoring experiment for mildly pathogenic E.coli)*
13. *Mu-mediated fusion of the LacZ gene to other promoters (Casadaban's experiment).*

Teaching staff will include:

S. Falkow (Seattle), J.-P. Hernalsteens (Brussels), M. Holsters (Gent), M.V. Montagu (Gent), P. Nevers (Braunschweig), D. Pfeifer (Cologne), H. Saedler (Cologne), J. Schell (Cologne), P. Starlinger (Cologne), I. Saintsirons (Paris).

Applications are requested until April 30, 1980, to P. Starlinger, Institut für Genetik der Universitättzu Köln, Weyertal 121, 5 Köln 41. Tel: 470/2465.

Circle No. 12 on Reader Enquiry Card.

HIGHEST STANDARD OF QUALITY IN BIOLOGICAL REAGENTS FOR THE STUDY OF NUCLEIC ACIDS, SYNTHESIS AND PROCESSING.

RIBONUCLEASE H–1
(From Calf Thymus)

This enzyme can be effectively used:
1. In the digestion of RNA moiety of the hybrid after Reverse Transcriptase Assay to avoid the deamination of cytidine in the CDNA, resulting from the alkalihydrolysis of the RNA moiety;
2. In the removal of the poly (A) stretches found on the RNA messengers;
3. As a restriction enzyme trideoxynucleotides in the DNA matrix, since it will exclusively attack the guanosine moiety of the RNA. Most of the RNA do not hybridize with trideoxynucleotides because they are double stranded. Only the regions at the single stranded loops can by hybridized with the deoxytrinucleotides so that only a few nicks in the RNA molecule will appear after the hybridization with the deoxynucleotides and subsequent treatment with RNase H.

Cat. No. EER-C $315.00/500 units $195.00/250 units $95.00/100 units

RIBONUCLEASE PHY I
(RNase I from Physarum polycephalum)

This novel enzyme preferentially digests G, A and U residues, allowing discrimination between C and U in RNA sequencing methods (1,2). This makes possible sequencing of terminally labeled RNA by the gel method (2).

One arbitrary unit gives partial digestion of 1 microgram of RNA under conditions described in ref. (2).

Cat. No. ERN-PHY $145.00/100 units

(1) Gupta, R., and Randerath, K. (1977). Nucleic Acids Res. 4, 3441.
(2) Simoncsits, A., Brownlee, G.G., Brown, R. S., Rubin, J. R., and Guilley, H. (1977). Nature 269, 833.

E. COLI RIBONUCLEASE H

Specific Cleavage of the RNA Strand of RNA:DNA Hybrids, e.g. in RNA:DNA Hybridization Reaction; Detection of Hybrid Structure; Removal of poly (A) tails from Eukaryotic mRNA using poly (dT). Assayed for freedom from E. Coli RNase Activities Including RNase III.

Cat. No. ERN-H $95.00/20 units $195.00/50 units

E. COLI RIBONUCLEASE III

Specific Cleavage of Pro- and Eukaryotic RNA's Detection and Quantitative Determination of Double-stranded RNA Specific Processing to Generate Authentic Phage T7 Early mRNA. Assayed for Freedom from E. Coli RNase Activities Including RNase H.

Cat. No. ERN-D $95.00/20 units $195.00/50 units

PATENT DOCUMENTATION

ALFRED WITTMANN, RUDOLF SCHIFFELS and MICHAEL HILL

Patent documentation is a fast developing field. This book offers a complete guide to documentation and acts as a source of technological information for a wide range of people in research, industry and commerce as well as for members of the patents profession.

From an organisational point of view, patents occupy an important place within the framework of the Committee for scientific and technical information and documentation (CIDST). Hence the role and features of patent documents are considered and there are detailed chapters on computerised bibliographic data bases, with comprehensive examples, abstracts, documentation within Patent Offices, management of collections, methods of patent searching and future developments.

Patent Documentation is an authoritative and informative aid for all who are concerned with this important field.

Proven alternatives...

...for progesterone recepter assays

For optimum binding, there is nothing better than hot progesterone in conjunction with cold cortisol[1]. For application where a synthetic steroid is preferred, recent papers indicate that ORG 2058 is the one of choice.[2,3] Amersham now offers:

[1,2,6,7,16,17-^{3}H]**Progestrone** TRK.641
120-160 Ci/mmol
[^{3}H]**ORG 2058*** TRK.629
40-61 Ci/mmol

The first issue of
Carcinogenesis

THE NEW MONTHLY JOURNAL
FROM IRL

Contents of Volume 1 Number 1 include:

Studies in Vitro to Discern the Structural Requirements for Carcinogenicity in Analogues of the Carcinogen 4-Dimethylaminoazobenzene (Butter Yellow)
J Ashby, J A Styles and D Paton

The Repair of Human DNA Following Fractionated Doses of Ultraviolet Irradiation
R Waters

Metabolic Activation of Benz(a) anthracene: Fluorescence Spectral Evidence Indicates the Involvement of a Non-'Bay-Region' Diolepoxide
P Vigny, M Kindts, M Duquesne, C S Cooper, P L Grover and P Sims

Biological and Chemical Studies on 8, 9-Dihydroxy-8, 9-Dihydro-Aflatoxin B_1 and some of its Esters
B F Coles, A M Welch, P J Hertzog, J R Lindsay Smith and R C Garner

Studies on the Macromolecular Binding of Benzidine
C N Martin and S F Eckers

Human Tumor Cell Strains Defective in the Repair of Alkylation Damage
R S Day III, C H J Ziolkowski, D A Scudiero, S A Meyer and M R Mattern

An In Vitro Metabolic Activation Assay Using Liver Microsomes in Diffusion Chambers: Induction of Sister Chromatid Exchanges and Chromosome Aberrations by Cyclophosphamide or Ifosfamide in Cultured Human and Chinese Hamster Cells
C C Huang, K McKernan and J R Sirianni

Biotransformation of 7, 12-Dimethylbenz(a)anthracene by Mouse Epidermal Cells in Culture.
J DiGiovanni, A Viaje, S Fischer, T J Slaga and R K Boutwell

The Formation of Azoxymethane, a Colon Carcinogen, During the Chemical Oxidation of Methylamine
E S Fiala

N-Ethyl-N-Formylhydrazine Tumorigenesis in Mice
B Toth and D Nagel

Variation in Route of Microsomal Activation of 7, 12-Dimethylbenz(a)anthracene with Substrate Concentration.
C A H Bigger, J E Tomaszewski and A Dipple

The Effects of a Single Dose of Dimethylnitrosamine in the Chinese Hamster and the Persistence of DNA Alkylation Products in Selected Tissues
G P Margison, J A Swindell, C H Ockey and A W Craig

Persistence of Alkylated DNA Bases in the Mongolian Gerbil (Meriones unguiculatus) Following a Single Dose of Methylnitrosourea
P Kleihues, S Bamborschke and G Doerjer

Interaction between Polcyclic Aromatic Hydrocarbons, Crude Oil and Oil Dispersants in the *Salmonella* Mutagenesis Assay
F L Petrilli, G P DeRenzi and S DeFiora

The removal of Alkylation Products from the DNA of *Escherichia coli* Cells Treated with the Carcinogens *N*-ethyl-*N*-Nitrosourea and *N*-methyl-*N*-Nitrosourea : Influence of Growth Conditions and DNA Repair Defects
W Warren and P D Lawley

GUIDE TO AUTHORS

- Review articles should be aimed at a relatively wide readership. Many reviews are invited, but submitted articles may also be accepted; it is advisable to consult us before writing a review article.
- Articles may be up to 3,000 words long with at most six displayed items (figures and tables); they are reports of major research developments.
- Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words; they have at most three or four displayed items.
- 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*.

Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusion in terms intelligible to as wide a readership as possible.

Manuscripts may be submitted either to London or New York. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should be identified in the margin on their first appearance. Equations should occupy single lines if possible: exp (a) is preferred to e^a if 'a' is more than one character.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) only one reference number need be used if the reference is to several papers by identical authors.

(ii) first and last pages of references should be cited.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth edn (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated 'Personal communication' and 'unpublished' should be incorporated in text.

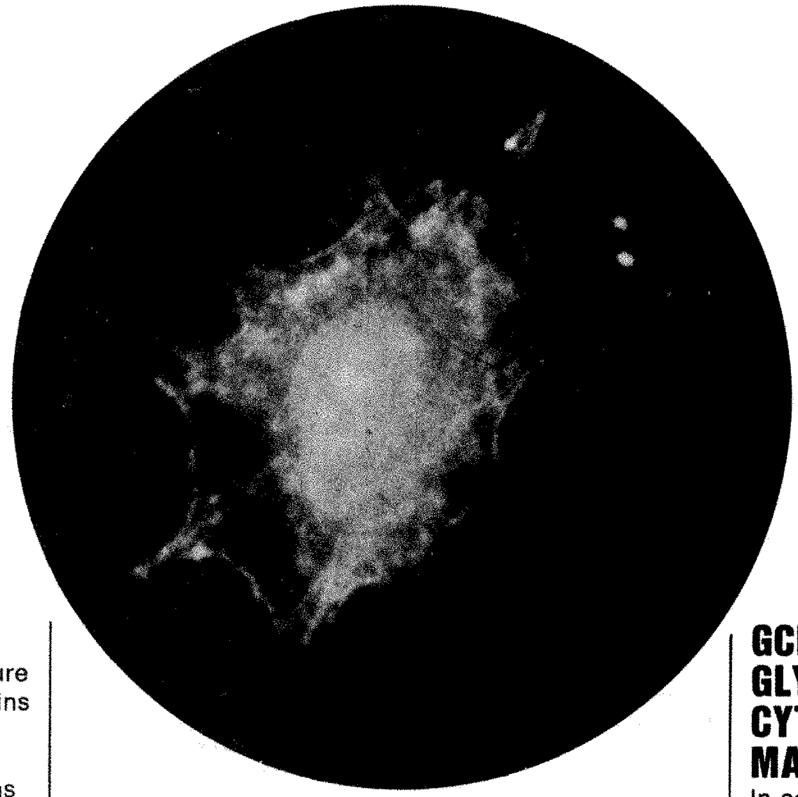
Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. Ideally, an unaltered original and three lettered copies should be provided; labelling on halftones should, if possible, be avoided entirely. Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Nature's publishing policy is outlined in **258**, 1 (1975) and **264**, v, 11 Nov. (1976).

Enjoy your studies on complex carbohydrates

LECTINS AND GCM FROM IBF



NATIVE LECTINS

Specificities of our 15 pure and salt-free native lectins satisfy to most of immunological and biochemical applications of lectins. Limulin from *limulus polyphemus* is our last new-born.

FLUORESCENT LECTINS

Our Flu-and Rho-lectins contain at the minimum 2 moles of covalently-bound DTAF or RITC per mole of native lectin. Their high stability and excellent conservation make them quite suitable for quantitative assays (SCATCHARD's plot).

IMMOBILIZED LECTINS

5 lectins of essential interest in affinity chromatography have been immobilized on glutaraldehyde-activated ULTROGEL AcA 22; this coupling method provides an excellent binding stability between lectin and gel and therefore avoids any ligand leakage.

GCM : GLYCOSYLATED CYTOCHEMICAL MARKERS

In addition to lectins, GCM were defined as tools for the specific visualization of surface and intracellular carbohydrates by light and electron microscopy; they are also suitable to visualize membrane lectins.

MONOCLONAL ANTIBODIES MONOCLONAL ANTIBODIES

New England Nuclear has begun a major new development program in the exciting new field of monoclonal antibodies for immunological research. To date we have introduced Monoclonal Anti-Thy 1.2 and 1.1 and Anti-Lyt 1.1 and 2.1. In process are fluorescein-labeled monoclonal antibodies and fluorescent-labeled native antibodies.

These high-titer mouse immunoglobulins are extraordinarily specific for cell surface markers of T lymphocytes. They are proving invaluable for the identification, localization, and selective isolation of mouse T-cell lymphocytes from mixed populations.

Let us send you current information and keep you informed of future availabilities. Simply circle the reader inquiry number.

Steady-State Enzyme Kinetics

Stanley Ainsworth

Identifies the basic ideas of the subject for the graduate and advanced undergraduate student, and familiarises the reader with them so that they may then be applied to any problem likely to be encountered. Although it cannot altogether avoid mathematical presentation, almost all the equations used require only an elementary acquaintance with algebraic manipulation. Moreover the arguments themselves are presented as fully as possible to enable the reader to progress easily from each stage to the next.

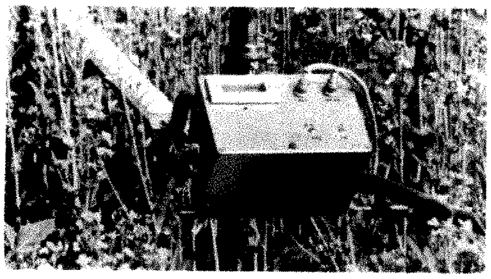
Instruments for the Botanist

T-METER

Gives direct digital readout of average photosynthetically active radiation within crop canopy as percentage of incident radiation. Available with quantum or level response sensors.

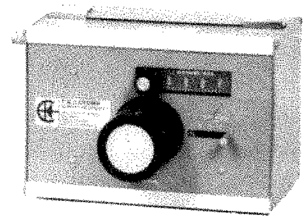


LOW VALUE CALIBRATION PLATE

For use with the Crump 502 Automatic Porometer to give accurate reproducible leaf water-loss measurements in plants exhibiting low diffusive resistance. Five low-value positions conveniently arranged in porous plastic plate.

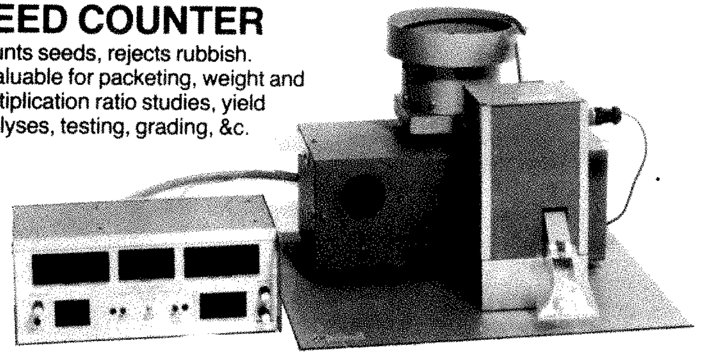
SPECTRORADIOMETER MODULE

Plugs into radiometer amplifier for measurements of narrow wavebands within the range 400-750nm. High-stability large area photodiode with well-proven wedge interference filter monochromator, high quality optics. Panel-mounted controls for wavelength and slit width setting.



SEED COUNTER

Counts seeds, rejects rubbish. Invaluable for packeting, weight and multiplication ratio studies, yield analyses, testing, grading, &c.



All Crump products are developed by botanists for botanists. And they're all British. Ask for details today!

GUIDE TO AUTHORS

- Review articles should be aimed at a relatively wide readership. Many reviews are invited, but submitted articles may also be accepted; it is advisable to consult us before writing a review article.
- Articles may be up to 3,000 words long with at most six displayed items (figures and tables); they are reports of major research developments.
- Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words; they have at most three or four displayed items.
- 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*.

Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusion in terms intelligible to as wide a readership as possible.

Manuscripts may be submitted either to London or New York. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should be identified in the margin on their first appearance. Equations should occupy single lines if possible: exp (a) is preferred to e^a if 'a' is more than one character.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) only one reference number need be used if the reference is to several papers by identical authors.

(ii) first and last pages of references should be cited.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth edn (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated 'Personal communication' and 'unpublished' should be incorporated in text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. Ideally, an unlettered original and three lettered copies should be provided; labelling on halftones should, if possible, be avoided entirely. Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Nature's publishing policy is outlined in **258**, 1 (1975) and **264**, v, 11 Nov. (1976).

ANNOUNCEMENT

Just before the IVth International Cyclic Nucleotide Conference: NATO Course

"CONTROL OF THE GROWTH AND FUNCTION OF DIFFERENTIATED AND CANCER CELLS BY INTRACELLULAR SIGNALS"

Organized in Nivelles (near Brussels) from: the 14th to the 23rd of July

SUBJECT MATTER

— The interaction of extracellular signals (hormones, neuro-transmitters, etc . . .) with their target receptors and cells

— The control and measurement of intracellular signals (calcium, cyclic AMP, cyclic GMP, etc . . .)

— The action of intracellular signals (through protein kinases, calmodulin, etc . . .)

— The fundamental biochemical background of studies in cell regulation: theory and methodology of hormone receptor interaction, contractile and structural proteins, mechanism of cell transformation, etc . . .

The following lecturers have already agreed to participate:

B. BROWN (London), A. ROBISON (Houston), R.W. BUTCHER (Houston), J.P. PERKINS (Chapel Hill), R. PAOLETTI (Milano), E.J. NEER (Boston), J.G. HARDMAN (Nashville), N.D. GOLDBERG (Minneapolis), D. SCHULSTER (London), G. SCHULTZ (Heidelberg), G. BROOKER (Charlottesville), G.I. DRUMMOND (Calgary), S. SWILLENS (Brussels), J. HANOUNE (Paris), J.E. DUMONT (Brussels).

FELLOWSHIPS ARE AVAILABLE

What's better than microgranular DEAE cellulose?

DEAE-Sephacel®
Bead formed, preswollen cellulose ion exchanger
Pharmacia Fine Chemicals
500 ml
Lot No. 9449
Pharmacia Fine Chemicals AB Uppsala Sweden

recycling	not required
ecantation	not required
acking	easy and rapid DEAE-Sephacel is ready to pack from the bottle
esolution	Superb, due to small spherical particles and ease of packing
eproducibili	Excellent from run to run and batch to batch
apacity	Very high for both large and small molecules

DEAE-Sephacel®

Get *all* the advantages of a cellulose ion exchanger. Find out more from the booklet "DEAE-Sephacel, Beaded cellulose ion exchanger", available free on request from Pharmacia Fine Chemicals or your local supplier.

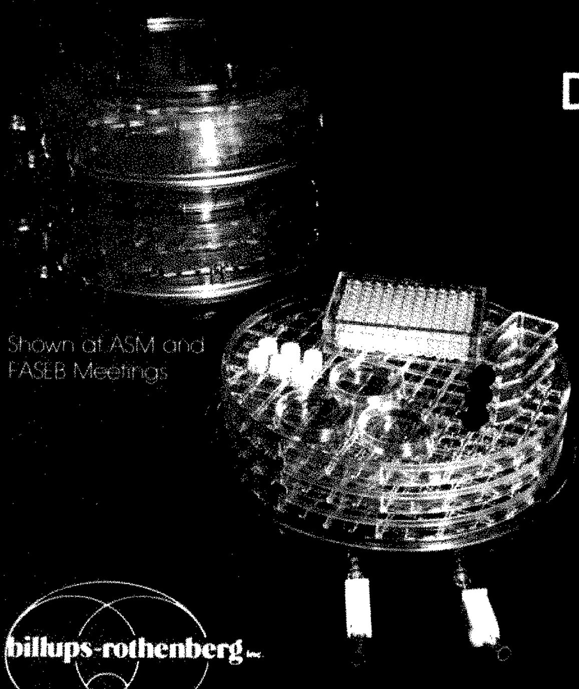
At Last! A Reliable Incubator Designed for Aerobic or Anaerobic Tissue Culture Experiments



Shown at ASM and FASEB Meetings

With this Modular Incubator Chamber* you no longer have to worry about the inherent variability (due to CO_2, temperature and humidity fluctuations) of present day continuous flow and anaerobic incubators.

Simply place your experiment into the sealed chamber, purge the system with the required gas mixture and set in a controlled temperature environment.

Because each chamber is an isolated system you now have the flexibility to design experiments you previously thought were impractical or too expensive.

Chamber and tray components are made from rugged, non-toxic, uv resistant polycarbonate.

Multi purpose trays conveniently hold petri dishes, test tubes, T.C. flasks, microtest plates, etc.

Chambers can be stacked and interlocked for agitation or storage.

To order or for further information phone or write Billups-Rothenberg, Inc., Dept. N.I., P.O. Box 977, Del Mar, CA 92014 USA (714) 755-3309.

GUIDE TO AUTHORS

- Review articles should be aimed at a relatively wide readership. Many reviews are invited, but submitted articles may also be accepted; it is advisable to consult us before writing a review article.
- Articles may be up to 3,000 words long with at most six displayed items (figures and tables); they are reports of major research developments.
- Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words; they have at most three or four displayed items.
- 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*.

Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusion in terms intelligible to as wide a readership as possible.

Manuscripts may be submitted either to London or New York. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should be identified in the margin on their first appearance. Equations should occupy single lines if possible: exp (*a*) is preferred to e^a if '*a*' is more than one character.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) only one reference number need be used if the reference is to several papers by identical authors.

(ii) first and last pages of references should be cited.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth edn (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated 'Personal communication' and 'unpublished' should be incorporated in text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. ideally, an unlettered original and three lettered copies should be provided; labelling on halftones should, if possible, be avoided entirely. Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Nature's publishing policy is outlined in **258**, 1 (1975) and **264**, v, 11 Nov. (1976).

GROWTH WITHOUT ECODISASTERS

N. Polunin

The environment is under attack. Its resources have been plundered to sustain industrial and technological growth. If growth is to continue and man is to live in a pleasant and healthy environment its use must be carefully planned and controlled.

The 18 chapters in this book are based on the keynote papers, and the discussions that followed them, presented at the 2nd International Conference on Environment Future held at Reyjavik in 1977. Papers, each of which was presented by a specialist in the field, range from Fresh waters and their biota to Life-style alternatives and the Ethics of biospheral survival.

£17.00 0 333 235515

THE CHAIN STRAIGHTENERS: FRUITFUL INNOVATION – THE DISCOVERY OF LINEAR AND STEREO-REGULAR POLYMERS

Frank M McMillan

The story of the remarkable burst of scientific discovery and technological innovation that gave science mastery over the 3-dimensional structure of high polymers and the world its most useful group of plastics and synthetic rubbers. A story surrounded by controversy, where science meets big business and powerful personalities clash. This will undermine many of the conventional views of scientific innovation.

£9.00 0 333 259297

FROM DNA TO PROTEIN: The Transfer of Genetic Information

Maria Szekely

This is the first textbook which discusses gene structure on the basis of recent discoveries of overlapping and split genes and which gives a consistent image of the ways in which genetic information can be encoded into the genetic material and how it can be transfered to other materials.

A perfectly up-to-date account of our present knowledge of the structure and expression of genes in prokaryotic and eukaryotic organisms and the only available text showing the correlation between the structure and function of nucleic acids.

Nuclear power: the critics must be heard

WHEN announcing the UK government's decision to build at least one nuclear reactor per year during the decade beginning 1982 (see page 3) Mr David Howell, Energy Secretary, placed great emphasis on the need for safety.

After the accident at the Three Mile Island nuclear power plant in Pennsylvania, US last March, public fears about the safety of nuclear power are justifiably strong. And in the UK, that fear is likely to be heightened by the government's probable intention to base the new programme on the pressurised water reactor — of a similar type to that at Three Mile Island — rather than the UK developed advanced gas cooled reactor.

Mr Howell was therefore right to stress the need for safety and to reaffirm the government's intention of holding a public inquiry on the safety of the PWR before the first is built. This view is endorsed by the new House of Commons Select Committee on Energy which recently announced that the PWR is to be its first topic for study. It is to call on Mr Howell and representatives from the nuclear industry and the nuclear opponents as witnesses and is to pay special attention to safety.

However, what will be most important over the next two years leading up to the public inquiry and indeed, throughout the subsequent construction of any power stations, is that Mr Howell's promise is seen publicly to be adherred to. The need for the nuclear industry to be entirely open about its plans is greater now than it has ever been. This is not the time for it to hide behind the government's decision in the hope that it will be out of the limelight. More than ever before, public attention will be turned on it and the public will expect its opinions to be taken into account.

The major lesson which must be learned from previous nuclear debates in many countries is the need for the critics of nuclear power to have complete access to information. We endorse the government's decision to release unabridged safety reports on all nuclear power stations but would go one step further. We recommend that the Nuclear Installations Inspectorate consider the opinions of the serious nuclear critics during any future safety assessments of nuclear power stations. This means that the critics must have the same rights of access to design and safety documents and the same rights to make site inspections as do NII inspectors.

Greater openness will not be to the detriment of the nuclear industry. On the contrary, an industry which is seen publicly to be taking the right decisions about safety is one which will receive support at home and orders from abroad. Where safety is concerned, the industry should not worry about the need for commercial secrecy because the industry which is the most successful in demonstrating the safety of its reactors will be the one most successful in selling them.

Finally, the current decision should not automatically lead to the first step along the road to a major commercial fast breeder reactor programme. Rather it should be seen as a way of keeping our options open well into the 1990s. In the meantime, research — and particularly the development — of alternative sources of energy and new uses for coal should be stepped up. Only after equivalent funding will it be possible to make a balanced judgement between — say — fast breeders and wave power. ☐

David Davies' editorship ends

FOR six and a half years *Nature*, and much of the world's scientific community, has enjoyed Dr David Davies' work as its editor. A man of character, he has impressed his personality and leadership on the journal. A firm believer, as I am, that the specifically human characteristic of adaptability requires change to express itself, to lead to the maximum contribution and real job satisfaction, he has always lived by his precept.

Once again, he felt that the time had come to move on to a radically different activity. He has become director of the newly established northern centre for the Dartington Trust, at Barnstaple, Devon. Much as we will all miss him from his editorial desk, his new task of nurturing vitality and amenities in the rural parts of North Devon will certainly give full scope to his drive and creative thinking.

He came to *Nature* from work as a geophysicist in MIT's Lincoln Laboratory in the US, with particular concentration on the intricate field of the seismic discrimination and the detectability of underground nuclear explosions — efforts continually central to the much hoped for complete test ban treaty. He had come to geophysics from physics at Cambridge University.

He threw himself into his new tasks at *Nature* with characteristic flair and drive. His international outlook, the result of much travel and experience of work in two countries, was translated into efforts which matured into a remarkable success of making *Nature* a journal concerned with the progress, health, organisation and vitality of science in all countries of the world. We should perhaps be particularly grateful for the coverage of countries of the developing world, but his own intimate knowledge of the United States scene, his selection of correspondents in Canada and on the European continent, his ensuring the reporting of what goes on in the USSR and Eastern Europe, all this has lead to a global outlook of educational benefit to all *Nature's* readers.

Personally, I have most enjoyed his editorials, pithy, hard-hitting and relevant. One may not have agreed with every one of them, but none was dull. But the journal's success is above all based on the original science it contains. It was no mean effort to have kept and increased its attraction to scientists everywhere for the rapid but responsible publication of relevant new advances. To have added to this central core of original letters a series of important and novel review-type articles in every issue has materially added to the value of the journal. The book reviews too have been a source of much enjoyment and profit to me.

His six and a half years with *Nature* have made an impact on all its readers. We all wish him well in his new and very different tasks.

Hermann Bondi

United States

NAS calls for global aerosol ban

An international ban on non-essential uses of chlorofluorocarbon (CFC) aerosol propellants is now the most effective way to reduce the dangers to health and food supplies from further depletion of the ozone layer — says a report published by the National Academy of Sciences. **David Dickson** reports.

THE US banned aerosol spray cans a year ago, and this has led to a 50% drop in the use of CFCs.

The report points out that there remain many other uses of CFCs — for example in automobile air conditioning units, or in the production of flexible plastic foam cushioning — equally in need of control. Such non-propellant emissions could bring the total CFC emissions back up to previous levels within seven to ten years.

Reducing such uses, however, is likely to be difficult, since in many cases there are no acceptable substitutes. But the report points out that progress could be achieved if other industrialised nations would agree to a ban on non-essential aerosols: "should all countries decide to take action comparable with that already taken by the United States and Sweden, between one third and one half of the world's present CFC released would be avoided.

"Such a reduction would be a great step forward in decreasing the threat to the world's food supply, even though the magnitude of this threat is uncertain, and its advantages would far outweigh the relatively small costs of substituting alternative propellants and devices."

The report was prepared by the Committee on Impacts of Stratospheric Change and the Committee on Alternatives for the Reduction of Chlorofluorocarbon Emissions of the Academy's National Research Council. It was commissioned by the US Environmental Protection Agency.

Its strong message adds further fuel to the controversies that have been building up in other industrialised countries since the hypothesis that CFC emissions could seriously deplete the ozone layer — subsequently increasing the exposure of humans, animals and plant-life to harmful ultra-violet radiation — was first raised by US scientists in 1974.

Two months ago, another academy committee confirmed earlier conclusions that, if emissions continue at the present rate, the amount of ozone in the atmosphere is likely ultimately to be depleted by about 16%, half taking place within the next 30 years.

A few countries, in particular Sweden and Norway (expected soon to be joined by Canada) have agreed to follow the US example. But West Germany, France, the UK, Japan and Italy (who, together with the US, account for 90% of the West's production of CFCs) have refused to impose stringent controls.

There are signs that their position may be shifting. Member countries of the European Economic Community, for example, which earlier this year agreed voluntarily to reduce non-essential aerosol usage by 30% by 1982, last week agreed to advance the date by six months, and to hold back on additional investment in industrial uses of CFCs.

The US however, would like things to move much faster. The report recommends the complete elimination of non-essential aerosols on a global basis. Dr John W Tukey, of Bell Laboratories, chairman of one of the panels, said last week: "The US has done it, and it wasn't very painful."

The new report examines in detail some of the consequences of the depletion in the ozone layer predicted by the companion study. And it discusses some of the alternative technologies, such as sealed air conditioning units, that might reduce or replace CFC-emitting processes.

The most obvious human health effect, it says, would be a further increase in skin cancer, (melanoma), already one of the most rapidly increasing forms of cancer in the US. The report predicts several thousand more cases of melanoma a year, "of which a substantial fraction would be fatal."

But the committee expresses greatest concern over the effect on global food supplies. "Here we know enough to be concerned, but not enough to predict what the biological effects would be," says Dr Tukey.

As DNA is affected by exposure to solar ultra-violet radiation the effect on the growth and reproduction of animals and plants would be expected to lower the yields of farms and fisheries.

Experiments indicate that some crops, such as sugar beets, tomatoes and corn, might be "significantly affected" by a 16% ozone depletion.

The report points to the particular threat to aquatic food systems studies of the UV sensitivity of young anchovies indicate that this commercially-important food source now lives near the limit of its solar-UV tolerance when at the surface of the water, as do certain crab and shrimp larva. "A 16% reduction in ozone concentration would be distinctly harmful to them in a surface location," it says.

Discussing the non-aerosol uses of CFCS, the report says that in many cases alternative technologies already exist, in particular for the agents used in blowing flexible pastic foam, and for the solvents used for cleaning metal or for sterilising medical supplies.

In other cases, however, controlling the use of CFCS is not likely to be so simple. It picks out their use in automobile air conditioning systems, the larges single sources of CFCS remaining in the US.

The prospects of reducing emissions from this source are "not good", though modifications to minimise leakage could yield significant reductions without burdensome costs.

The report outlines a variety of measures to restrict non-aerosol uses, from a complete ban on certain applications — the simplest approach, but "not always advantageous" — to a judicious mixture of tax measures, quotas on specific uses, and public edcuation.

The ozone problem differs from earlier environmental threats, since wherever CFCs are emitted, the ultimate effect is global. It is therefore the forerunner of another serious problem: the increased atmospheric concentration of carbon dioxide. It concludes: "the nations of the world collectively need to devise mechanisms for dealing with problems of this sort, assessing the scientific evidence as it develops and finding ways to agree on effective control actions, since these are not problems that can be adequately dealt with by the actions of only a few nations." □

Heavy water reactors are less proliferation resistant

Although making more efficient use of uranium, heavy water reactors are less proliferation resistant than either high temperature gas-cooled reactors or light-water reactors, according to the draft report of the US Department of Energy's Non-Proliferation Alternative Systems Assessment Programme. The report, published last week in Washington for public comment, suggests that AGRs might have an application in the industrial process-heat market. In general, however, it suggests that the US can minimise the risks of proliferation by pushing ahead with the development of LWRs, and with liquid-metal fast breeder reactors. "In order to influence the liquid-metal fast breeder reactor programs of other countries, not only must the US be a member of the fast-breeder development community, but it also needs to exercise leadership in developing the technological measures which would reduce the poliferation risk of fast breeder reactors," the report says.

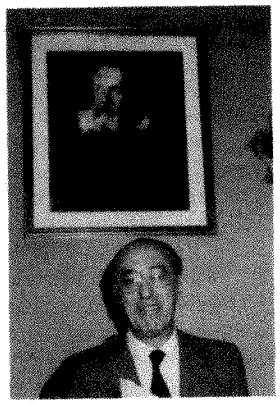
Italy

Confronting the Euro agencies

Vito Scalia, Italy's science minister, alerted *Nature* shortly before Christmas (see 20 December p 768) to the three-pronged attack he was to make on European research organisations. Speaking in the room in the Rome convent where Galileo was tried (right) Scalia demanded that Italy get fairer treatment from ESA, that CERN delay its decision on a new Director-General, and that the EEC adopt an experiment on nuclear reactor meltdown. The results of his efforts are now becoming plain, as **Robert Walgate** reports.



ITALY'S representatives at CERN, the European organisation for subnuclear research, withdrew from the 19 December Council meeting and refused to endorse the appointment of German Professor Herwig Schopper, as new Director-General from 1 January 1981.

The Italians are thus carrying out their threat to "consider seriously dissociating" Italy from CERN. One of the present joint CERN Directors-General, Dr John Adams, offered to visit Rome to mediate in the dispute — which is principally between Italy and Germany — but Rome refused.

The delegation is apparently still smarting from the rebuff it received — at a preliminary meeting — to its proposal that the future programmes of CERN should be "better clarified" before an appointment is made. Italy fears that Germany is not altogether sincere in its commitment to CERN's future, as it is considering a proposal for an accelerator (HERA) that Italy believes is competitive with CERN's LEP (see page 5).

The Italian government has its own candidate for the CERN Director-Generalship, Professor Antonino Zichichi. But Italian scientists working at CERN were nervous of their delegation's tactics, as they rely on CERN and other non-Italian laboratories for their livelihood.

JET under threat

THE European Commission's Super Sara experiment on nuclear reactor meltdown is now supported by eight of the nine community members, with only France objecting.

At a meeting in Brussels of energy ministers of the nine, Italy — the strongest supporter of Super Sara — swung a number of other objectors (including Britain) behind her. But Pierre Aigrain, France's Minister of Science, continued to hold strong objections.

France claims that its similar experiment at Cadarache is more advanced than Super Sara — which would be conducted at the EEC Joint Research Centre at Ispra, north Italy, on an isolated circuit within the reactor ESSOR.

France's objections have led Italy to act on its threat to hold up once again the EEC's 1980-85 budget for energy research.

ESA absorbs objections

ITALY'S attack on European research organisations succeeded in one respect: a tacit agreement of the Council of the European Space Agency to adjust the budget in Italy's favour to the tune of 27 million units of account (mua) (about $40 million).

Italy had argued that it had lost some 32 mua over the allocation of contracts to build Spacelab, the orbiting laboratory which will be flown by the Space Shuttle.

The adjustments should be confirmed at a meeting on 23 January. They will come in the form of a reduced contribution over four years, and a greater allocation of Spacelab follow-on projects. ☐

United Kingdom

Government plumps for PWR power station

THE UK government has decided to embark on a major new nuclear programme. At least one nuclear power station is to be built each year during the decade beginning 1982 and the nuclear industry is to be revitalised to cope with the demands to be made of it. The estimated cost of the programme — to be paid for by the Central Electricity Generating Board — is £10-12 billion at 1979 prices. It is expected to increase the nuclear contribution to electricity supply from 12% to over 30% by the early 1990s.

Mr David howell, Secretary of State for Energy, said when announcing the decision that the UK needed a nuclear programme of this size if it was to maintain the type of society it has now into the 1990s, when North Seal oil and gas production would decrease. The size of the programme, equivalent to about 15,000 MW, was based on Department of Energy forecasts of energy demand, assuming a 20% saving in consumption from conservation, he said.

A substantial programme was also needed to build up and maintain a strong industry; the lack of orders over the past decade had led to its decline. "If we are to reverse this trend and ensure that the industry is on a sound footing, we must act now", said Mr Howell. Under the reorganisation planned for the industry, the National Nuclear Corporation (NNC) and the Nuclear Power Company are to be brought under the umbrella of one board. The new NNC will then have total responsibility for management of all nuclear projects.

One of its first tasks will be the design of a pressurised water reactor under license from Westinghouse. In line with the previous Labour Government's decision, the Conservatives intend that the first power station of the programme will be a PWR. The design must be approved for safety by the Nuclear Installations Inspectorate and must be subject to a public inquiry. The NNC estimates that it could be ready for this by the end of 1981, and that construction could begin in 1982.

The NNC is also to assume responsibility for managing the UK's advanced gas cooled reactor (AGR) programme. By building two more AGRs as well as one PWR, the CEGB hopes that the final choice of reactor can be left for some time. However Mr Howell has said that a commitment to one system or the other would have to be made fairly early on in the programme.

The major advantage of the PWR over the AGR is capital cost. The CEGB estimates that the capital cost per MW is £750,000 for an AGR and £680,000 for a PWR.

● The British nuclear industry and the NII have released preliminary statements on the implications of the accident at Three Mile Island. They conclude that the recommendations of the President's commission, set up to investigate the accident, do not apply to the UK. Fault was found with the regulatory procedure in the US and the standard of operator training but not with the basic PWR design. Most of the suggestions for improvement, they say, are already incorporated in the UK regulatory procedure.

Brezhnev counts on Academy of Sciences to organise applied research

LAST month, the Soviet Academy of Sciences met to discuss the role of scientists in solving the urgent problems facing the national economy. This was on instructions from the Party Central Committee and the government, and was a response to Mr Brezhnev's November address to the Central Committee. In his swingeing attack on Soviet planning and production, Brezhnev singled out for castigation a number of ministries (including railways, power and ferrous metallurgy), the State Planning Committee and the "bureaucratic and local interests" which "weaken the strength of the plan". In tackling the "vital tasks", both of production and planning, said Brezhnev, the Party counts on the active assistance of scientists, the USSR Academy of Sciences, the Republic and branch academies and all scientific research institutes. "The State Committee for Science and Technology", he added, "must also work in a more energetic manner".

This is not the first time that Brezhnev has called on the academy for assistance. At the Twenty-Fifth Party Congress in 1976, he had declared that the academy was to act as cheif coordinator of all scientific work in the country. This caused some confusion, not least to the academicians themselves. It now seems certain, however, that what Brezhev meant was that the academy should coordinate fundamental research throughout the USSR, stressing the need to implement the practical applications of such research.

At the same time, a number of specialists from the academy were involved (together with officials of the State Planning Committee, the relevant ministries and the State Committee for Science and Technology) in working out a "complex programme" for the development of science and technology up to 1990. Work on this programme began in 1972, under the general direction of a special commission of the academy presidium, but by summer 1979 it was still not completed. In the course of work on the "complex programme", there have been numerous set-backs; perhaps the greatest being the change from forecasts for individual technologies with little coordination between them (some 150 in the first drafts) to 25 "integrated" programmes, 17 for science and technology and eight for social questions, covering broader fields such as energy, health, industrial materials, and demographic trends.

How far existing plans for the "complex programme" will be affected by the latest appeal to the academy is not clear. Addressing the assembly, the President of the academy, Anatolii P. Aleksandrov stressed the Soviet Union's continuous shortfall of ferrous metals, cement and fertiliser, the need to pay greater attention to the "economic utilisation" of energy, raw materials and agricultural produce.

Nikolai Baibakov, Chairman of the State Planning Committee and a Deputy Chairman of the USSR Council of Ministers, stressed the need for a long-term comprehensive programme for transport, including pipelines for pulp, pipelines using containers, magnetic suspension transport and linear motor trains. The automation of manual labour (a major problem for the Soviet Union with its falling demographic trend) was also stressed. Baibakov commended the academy's current research on energy-saving types of equipment and new types of polymer, which, he said, should ultimately save the economy some 1000 million roubles.

Media comments on the session, presumably from official releases, stressed the need for a new comprehensive plan for science and technology up to the year 2000, giving priority to new regions in the far north, Siberia, and the Soviet Far East.

Setting the tone for such developments, Baibakov noted that "socialist planning has always been 'target-orientated'", citing Lenin's plan to electrify the whole country, the construction of heavy industry in the 1930s, the Virgins lands scheme of the early 1960s, and the current construction of the Baikal-Amur Mainline railway.

His remarks have some suggestion that science and technology might take on the status of a "crash programme". (This would not be out of key with the economic "mini-reform" proposed last July). Aleksandrov, the President of the Academy has, incidentally, considerable experience of this type of priority development (nuclear research) as had his predecessor Mstyslav Keldysh (space). Such crash programmes have been particularly successful in sectors with some defence connections (since defence falls outside the main planning structure). Any attempt to introduce wide-scale crash planning would, however, appear to be counter-productive — there would be too many priorities competing for too few resources.

The main weakness of Soviet science planning, however, remains the point at which production takes over from research. Since the mid 1960s the planners have set considerable store on closer links between research and academic institutes on the one hand, and local farms or factories on the other. The classic case of such cooperation is the Siberian branch of the academy at Novosibirsk. Here a network of research institutes, design centres and experimental production factories has been set up. These are maintained by, and officially subordinate to, the relevant ministries, but the various institutes of the Academy of Sciences are responsible for the scientific leadership.

Recently, a number of *ad hoc* "science centres" were established throughout the Soviet Union, often simply by formally linking existing research and industrial establishments. Many of these centres, Baibakov told the academy, are "observed to be dissipating their resources" and wasting time on "second grade problems", which are not "in the mainstream of technical progress". As a result, "many ministries (presumably those censured by Brezhnev) have been unable to fulfil their plans for science and technology".

Since the Siberian branch of the academy was established, a number of academics, including its chairman academician G I Marchuk, have pointed out that the dual control system could lead to precisely this kind of dissipation. However, this has always been presented as a danger. By concentrating too much on the minutiae of day-to-day problems, the ministry could distract researchers and resources from basic and far-reaching tasks. Academician B Paton of the Ukrainian Academy of Sciences would prefer that even the design and pilot-production facilities should be subordinate to the academy, so as to obviate this hazard.

Baibakov's remarks, however, seem intended to exonerate the ministry planners and, perhaps, by implication, shift a greater responsibility to the academics. The relationship between the Academy of Sciences (traditionally orientated to fundamental research) and the state committee for Science and Technology, with its stress on production is always a delicate one. Although Brezhnev has censured the state committee and called once again on the academy's assistance, the state committee has recently taken over a duty which would normally be considered the prerogative of the academy. At the forthcoming Hamburg "scientific forum", where most of the Helsinki signatories will be represented by their academies of science, the Soviet delegation will be headed by the Chairman of the State Committee.

NEWS IN BRIEF

CERN discloses plans for new accelerator

LEP, a particle accelerator to collide 22-130 GeV electrons with their antiparticles, positrons, at the same energy, would begin construction near Geneva in early 1982 if plans announced at last week's CERN Council meeting are accepted. John Adams, Director-General of the Centre for european nuclear physics (CERN), said that he planned to submit a firm proposal for LEP to the Council — the supreme body of CERN on which all member states are represented — in June 1980. A decision could be taken in June 1981.

LEP would probably be 5 km in radius, and be built underground. It could be built without increasing the present CERN budget of 593 million Sw Fr per year, and no new staff would be needed, said Adams; but the intersecting storage rings (for proton-proton collisions) would be phased out, and the old 8 GeV synchrocyclotron — CERN's first machine — reduced to serve only the low energy physics 'Isotope separator on line' (ISOLDE), which is widely used by Scandinavian members of CERN and has produced much useful data on short-lived isotopes.

USSR to license use of advanced energy technologies

THE Soviet Union will license the use of 30 processes for eliminating the high sulphur content of coal and for developing electricity production through magnetohydrodynamics to the US. The agreement signed by the USSR foreign trade organisation Licensintorg and the US firm Control Data Corporation, is a consequence of a deal made several years ago when Control Data supplied a superconducting magnet to the USSR for use in MHD experiments. In return, Control Data saved the need to build a MHD test plant of its own.

US to stop funding labour-saving agriculture research

THE US Secretary of Agriculture Mr Bob Bergland, has announced that federal research funds distributed to land-grant colleges and universities can no longer be used to support research into the mechanisation of agricultural processes leading to reduced employment for farm workers.

Such research has come under increasing criticism in recent years for contributing to unemployment among farmworkers, particularly among migrant workers who had previously been dependent on seasonal agricultural work for a major proportion of their income. Critics charge that the federal research funds which are distributed to land-grant colleges on a pro-rata basis under the terms of the Hatch Act are merely serving to enrich large food-producing corporations.

However, Secretary Bergland's move was criticised by Dr Charles E Hess, head of the College of Agricultural and Environmental Science at the University of California, Davis, who said that "to suggest halting research which significantly contributes to enhancing agricultural productivity and efficiency is irrational and irresponsible."

France and China sign agreement on geological research

AFTER eight days of meetings and visits to Chinese laboratories, Pierre Aigrain, the French Secretary of State for Research, signed an agreement on 14 December with Deng Xiao-ping, the Chinese vice-Premier, to provide for Franco-Chinese cooperation in geological research. The agreement gives the go-ahead to three French missions to study the north slope of the Himalayas in 1981, 1982, and 1983. In return France will provide laboratory equipment for Chinese geological research. Other areas of possible cooperation are teacher exchanges, the evaluation by French specialists of Chinese mineral reserves, particularly chromium, and the establishment of a Chinese geological information bank. Mr Deng Xiao-ping called the agreement a step in the direction of correcting the "loss of scientific talent due to the Cultural Revolution".

Ariane makes it to the top

ARIANE, Europe's — but mostly France's — very own space launcher, went aloft on Christmas Eve (24 December) only 2 km away from its planned trajectory. A few days after the launch, measurements showed that the payload — a small test satellite — was in an orbit with perigee (closest approach to Earth) of 202.6 km, apogee (furthest distance) 36,019 km, with an inclination of the plane of the orbit to the equator of 17°.

The launch appeared to demonstrate that the hitches which caused the abandonment of two launch attempts within a week were indeed minor. They are attributed to small instrumentation malfunctions.

The greatest achievement — and surprise — of the launch was the perfect operation of the hydrogen-burning third stage, which had not yet passed its ground qualification tests.

European Space Agency press announcements before the launch had hedged around what would be considered a 'successful' launch, urging journalists to count mere ignition of the third stage a 'success'. There will be three more trials in 1980; one more 'success' will be considered a 'qualification' of Ariane for its first commercial launches in 1981.

GMAG invites proposals for scale-up

THE UK Genetic Manipulation Advisory Group has issued guidelines for work with recombinant DNA "involving volumes of 10 litres or more". All proposals for "scale up" will be judged on the basis of a site visit as such will be considered case by case rather than by a set of strict rules. GMAG will examine the biological aspects of proposals for "suitable levels of disablement and containment".

Physical plant will also have to be examined for pressure safety, leaks or cracking and safety and emergency procedures will be inspected as will sterilisation provisions for waste products. A GMAG official said that the requirements are not beyond industry's present procedures for biological manufacture as for example in vaccine and antibiotic productions. "We want to encourage not discourage applications. Industrial procedures are usually much safer than laboratory work and if the proposals are consistent with safety we would be quite happy".

Saccharin confirmed as weak human carcinogen

STUDIES carried out by the US National Cancer Institute have shown that heavy users of artificial sweeteners, especially those who consume diet drinks and other sugar substitutes, have a 60% increased risk of bladder cancer.

The study was based on interviews with more than 3000 bladder cancer patients and 6000 healthy people. It revealed "no increased risk" in the overall population being studied, but that those who used six or more servings a day of the sugar substitute saccharin, or two or more eight-ounce diet drinks, increased the risk of bladder cancer by 60%.

Following announcement of the results of the study, the Food and Drug Administration, whose attempt to ban the use of saccharin has been blocked by Congress, announced that it confirmed its previous contentions that artificial sweeteners posed a cancer risk to humans. Dr Jere E Goyan, Commissioner of the FDA, said that the study was consistent which previous animal studies and scientist's conclusions that saccharin is a "weak carcinogen", in particular acting in conjunction with other causes of cancer, such as cigarette smoking.

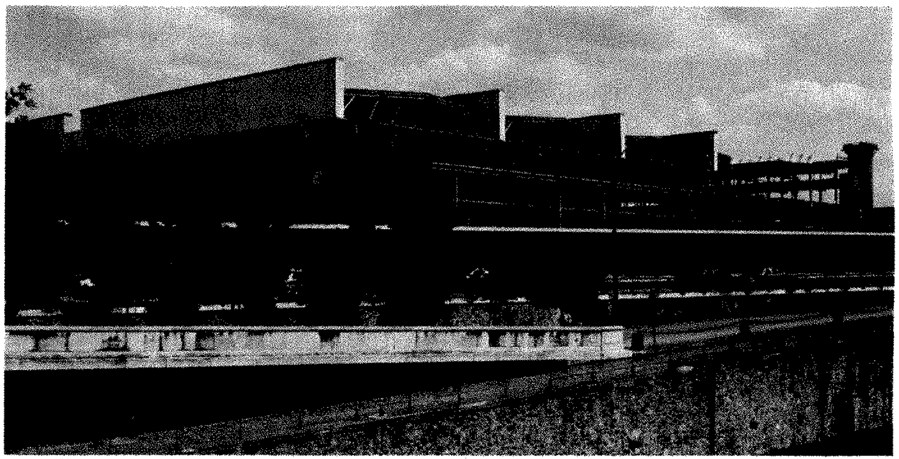
FEATURES

France plans new science museum

FRANCE is soon to publish a report proposing the construction of the largest science museum in the world. Compiled on the instructions of the President Giscard d'Estaing by Professor Maurice Lévy and a committee of 11, the report was completed last October after a 12-month study. However, Giscard d'Estaing has still not publicly released it; clearly there is a lively debate going on within the government about just how large a commitment France can afford to make to such a project at a time of economic squeeze. But there is no doubt that the project will go ahead in some form; even if money is hard to find, the advantages are too large to ignore.



La Villette: a possible home for the new science museum.

First, there is the location. A disused abattoir called La Villette squats in the north-east corner of Paris. Its grounds cover 52 hectares, making it the largest open space in Paris outside the Bois de Boulogne. Abandoned almost ten years ago, the prey of property speculation and grandiose schemes, La Villette has long been the biggest property scandal in Paris. Thus its planned transformation into a park and a new Museum of Sciences and Industry (with a concert auditorium to be added later) will remove a painful reminder of a rather disreputable past. The conversion could be ready in five years at an estimated cost of 363 million FF.

Second, there is the equally scandalous condition of Paris's present science museum, the Palace of Discovery. Housed in a crumbling building constructed in the 19th century as a "temporary" exhibition hall, much of the equipment dates from the 1930s when Jean Perrin created it. Conceived of as one of a series of museums, it had to crowd in examples of all the sciences when the plans for the others were abandoned. Perrin's idea of "familiarising our visitors with the fundamental research by which science is created, through daily re-creations of the great experiments" has, through lack of funds and support, largely degenerated into formal lecture-demonstrations by underpaid staff to audiences increasingly made up of reluctant schoolchildren and middle-aged professionals. Meanwhile, the Conservatory of Arts and Crafts, set up at the time of the Revolution to be a collection of all the "originals of instruments or machines invented or perfected" in France, has remained a hodgepodge of machines, with almost no representation of very old, or very recent technologies, or those not originating in France.

So the decision to build a new museum of science, in La Villette, has a compelling logic.

Professor Lévy sees the museum as a counterweight to the way science is taught and popularised in France. As in most countries, the public view science as a formalised, completed structure, rigidly demarcated as the domain of "experts", pursuing their unfathomable goals by unknowable means. In France this is particularly marked, and leads to a virtual absence of public debate on scientific and technological questions. The new museum, Lévy feels, must be the initiator of such debates. "Science", he points out, "is too important to be left to the scientists."

Hitherto, most museums have followed one of three patterns. One such is typified by the Palace of Discovery: the hierarchial initiation of the layperson into the mysteries of science by the "expert", the quasi-academic lecture and demonstration. The conservatory of Arts and Crafts is an example of the second type: a dusty collection of artefacts, the frozen detritus of past accomplishments. Finally, there is the third kind, found in most postwar museums, where there is a tendency to represent science as a series of disjointed tricks, black boxes which, when their buttons are pushed by the visitor, dutifuly trot out their magical effects.

But now modern technology and the increasingly sophisticated demands of the public, Lévy claims, has made possible "not an amelioration but a mutation" in the concept of a museum. New methods of communication will allow people to participate in scientific and technological decisions by giving them real access to the basic conceptual foundations of science and their practical consequences through active participation and debate.

This will happen in two ways. First, the flexibility of modern techniques permits "branching", the creation of an autonomous set of subthemes so that each museum visitor will be able to follow his or her own interests and needs in a certain subject, from basic concept to detailed application. Second, the museum at La Villette will make use of the "science in the streets" movement where scientists at conferences also present their ideas in local public forums, answering questions and stimulating debate. La Villette plans to take this up in the form of a series of weekend events held every two or three months in which scientists and technologists would engage the public at open meetings at the museum as equal partners in a discussion of the consequences of what they have done.

There are a number of questions however which have been raised about the project. Bertrand Gille, an eminent French historian of technology, has pointed out that the relations of science to technology is far from unproblematic. A lack of historical perspective, the propagation of the idea that there is "one" technology flowing effortlessly from scientific advance are "received ideas" which still inform much thinking about the new museum, and tend to undermine the possibility of the critical approach that the museum is supposed encourage. Furthermore, Michel Biezunski, one of the originators of the interactive computer systems forming the base of the museum, is concerned about the control of the content of the displays. The public depends on the information in the exhibitions, and since both science and industry have a vested interest in stressing the positive side, where is the space for informed, critical debate?

Answering these criticisms, Lévy insists that the museum will try to show science as a "human endeavour", possibly by the inclusion of examples of scientific failures as well as successes. Further, he also insists that the museum staff, not government or industry, control the content of all exhibitions. But doubts persist. It is, after all, in the very nature of a museum to present historical successes, for they have become "knowledge". It may be felt that few people would come to see displays of technical failure, even though such exhibits might really illuminate how science works.

UK underestimates cost of Trident deterrent

Britain has decided to renew its independent nuclear deterrent, probably by buying the submarine-launched Trident C-4 missile from the United States. **Judith Reppy**, Visiting Fellow at the Science Policy Research Unit at the University of Sussex, argues that this would be a questionable decision on economic grounds

AT present the British deterrent force consists of a fleet of four submarines armed with Polaris A-3 missiles that were supplied by the United States on terms well below cost in the 1960s, a largesse not likely to be repeated. The timing of the decision on renewing the deterrent is forced by the expected deterioration of the Polaris submarine hulls after 25 years of service, that is, by about 1993. Given the lead time needed for development and production of a new submarine, a decision is necessary soon. Postponement might mean abandoning the submarine-based deterrent, although choice of a different technology, such as air-launched cruise missiles, would imply a different timetable.

Coincidentally, NATO has just decided to push ahead with the modernisation of its 'theatre' nuclear weapons by deploying US Pershing II and Ground Launched Cruise Missiles (GLCMs); 160 of the latter will be based in England. Although in one sense these theatre missiles could be regarded as 'strategic' weapons — since like Polaris they will be able to reach targets within the Soviet Union — from an operational and financial perspective they are quite different. A new independent British deterrent force will be paid for by Britain, and, although it will be integrated into NATO forces, Britain will reserve the right to fire the missiles on its own. The theatre nuclear missiles will be assigned to NATO, but will be paid for by the United States and be under US control.

The decision to replace the Polaris fleet is first and foremost a political decision, based implicitly (for there has been no public discussion) on a certain view of Britain's status in the world and its relations with the US and its other NATO allies. The decision also has economic and technological consequences.

How much will a new submarine-based nuclear deterrent cost the British taxpayer? The operating costs of the Polaris fleet are not particularly large — only £126 million out of a total defence budget of £8,558 million in 1979 — but the investment in the design and production of a new submarine and missile will be heavy. Ian Smart in his 1977 Chatham House paper 'The Future of the British Nuclear Deterrent' estimated the cost of a replacement programme at £2,245-2,925 million at 1976 prices. That figure, swollen by inflation, stands now at perhaps £5,000 million for five submarines and their nuclear missiles.

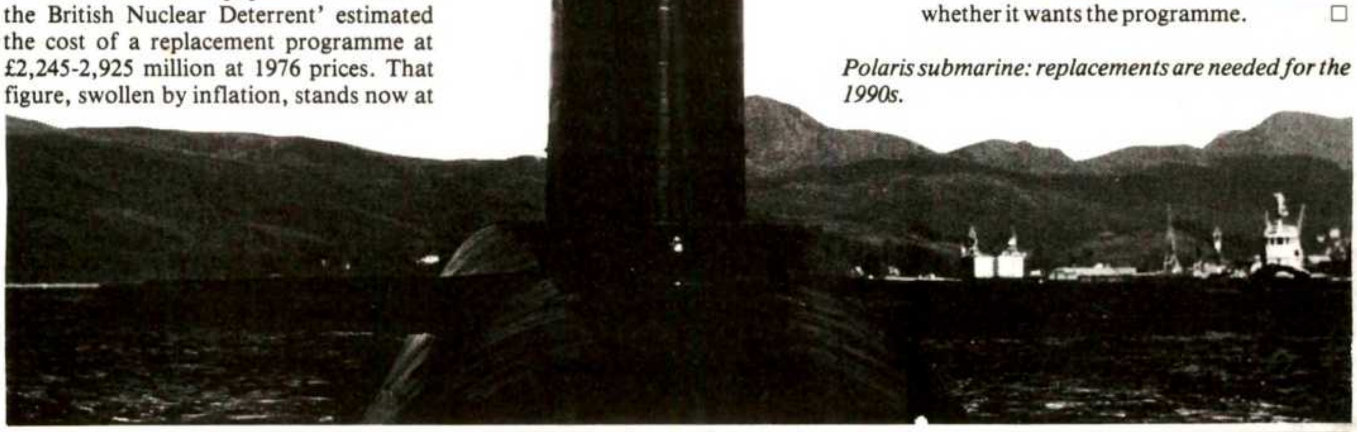
There is reason, however, to question whether even this sum will pay the costs of replacing the Polaris fleet. The United States expects to spend over $23,000 million (about £10,500 million) on a fleet of thirteen new submarines, and missiles; 62% of this is attributable to the cost of the submarine (see 'Trident — the US Experience: ADIU Report, Vol. 1 No 4, December 1979). The US Trident submarine is a huge boat, 560 feet long, and it has proved very expensive to build, costing over $1600 million (£730 million) per boat. But even though Britain would surely choose a more modest design, it is still likely that it would cost more than Smart's estimate. That estimate allocated only 40% of the total programme costs to the submarine, or roughly £240 million per boat (1976 prices). The US figure suggests that is too low.

British shipbuilding capacity has shrunk since the Polaris submarines were constructed in the 1960s, and only the Vickers Barrow yard now builds nuclear submarines. To build the new submarines at Barrow would take up capacity needed for other Navy programmes, whereas investing in new capacity elsewhere would entail costs not included in the Smart estimate. It can be argued that to invest in additional specialised industrial capacity to build five units of a product for which there is no other market would be economic folly.

Beyond these budgetary costs lie important opportunity costs, both with respect to other categories of public spending, such as education and health, and within the defence category itself. The share of the budget required for submarine design and construction will almost certainly pinch other elements of defence spending. Considering the emphasis placed on shortages of conventional weapons in the government's assessment of the military balance, it is perhaps surprising that tanks or air defence weapons are not considered a more urgent priority.

Given the large sums of money involved, the Trident decision also represents an important element in government funding for new technology. It is likely that the government will purchase the missiles from the United States, but develop and produce the warheads in Britain as was done for Polaris. Expertise in the technology of multiple independently targeted re-entry vehicles (MIRVs) will be acquired from the US. These capabilities, however, are not likely to spread into the civilian economy; they are too specialised for direct transfer, and the military market itself is so narrow that further internally-generated technological growth is not probable. The expenditure of more than £1,000 million on R & D for the Trident missile must be justified solely in military terms.

But the most disturbing aspect of the government's decision has been the absence of any public debate on the validity of the arguments for renewing the independent deterrent and the advantages and drawbacks of the various technological options. The public will pay the costs; it deserves a chance to consider whether it wants the programme. ☐



Polaris submarine: replacements are needed for the 1990s.

Science in the 80s: the need for political involvement

As Secretary of State for Education and Science in the last Labour Government, Mrs Shirley Williams (below) took an above average interest in the health of the scientific community. **David Dickson** talked recently to her at Harvard University, where she has just been a visiting fellow

DD: Ten years ago you wrote about the "party being over" for scientists. How do you feel that statement has worked out?

SW: Throughout the 1970s it has been more difficult for scientists to get money; to that extent my prediction was broadly right. In particular, the gradual reduction in per capita spending on the universities has meant that the British research councils have had to find a greater proportion of the total research expenditure than was the case in the golden years of the late 1950s and early 1960s. But I hadn't at the time thought that not only would the party be over, but that those who went to the party would be spending their time cleaning up afterwards — which seems to be the situation now. I hoped that we could get back to a steady, albeit modest, rate of growth, at least for the research councils; it's now clear that we will not see what I was hoping would be about a 3-4% real growth rate per annum over four to five years.

DD: What has been the main impact of economic stringencies in political terms?

SW: So far, the science budget has not tended to be very involved in either the politics of being cut or being expanded. It tends to stand slightly outside the rest of the political process, and therefore to run along with whatever is the overall tendency. In a period of expansion, the science budget tends to grow alongside; similarly it tends to contract during a period of contraction. And one of the things I was very anxious to do — and just succeeded in doing towards the end of my time as Secretary of State — was to cut the linkage between seeing the science budget as, in a sense, merely another expression of the "science and education" budget. I thought it had to be treated separately, because it had quite different cases to be made for it. I don't believe, for example, that the science budget is appropriately linked to the massive impact of demographic trends, on the education budget, whether rising as in the late 60s or now declining.

DD: What type of arguments did you use in Cabinet a year ago to obtain support for increased funding for research?

SW: I tried to explain in ways that would be understandable to the non-scientist — and to some extent I used myself as a litmus paper — what was going on in science, and what the prospects were for reasonable breakthroughs in some fields, or at least for some very fruitful work. Examples might be the work on laser technology being carried out by the Science Research Council, or the Medical Research Council's work in fields such as senile dementia and schizophrenia, research which offered some prospect of making substantial savings in the health service in the future, if one could find ways of treating people outside mental hospitals.

The idea was not necessarily to say "this is what the work being done is about" but rather "these are examples which readily lend themselves to being thought about in terms of their impact on other people's programmes". I didn't feel there had been a sufficient attempt to explain the research council's activities, as distinct from saying "here's the science budget; I want a 2% growth for it". In other words, there had not really been an argument about the priorities for scientific research as against the priorities for other things, such as defence or social security.

My own belief is that, although scientists don't like to think that research is involved in the political process, it has to be, at least to the extent that science is explained as proselytised about. It wasn't really necessary at the time of the great Robbins expansion of higher education in the 1960s, because the dual support system bore the expansion on its back. Now that system is threatened by demographic shifts, as well as the general cutting back of the higher education budget — which makes it important for scientists and the research councils to learn to put across what they are doing, and build up a lobby of support.

DD: Turning to the social aspects of scientific growth, how do you feel the relationship between the scientific community and the political community has changed in the 70s?

SW: In the narrow sense of the two communities, I would firstly sum it up by saying that the scientific community resisted getting involved, or even communicating much, with the political community, and it certainly seemed to me that such communication was very important. The process under which, for example, the science and technology committee of the House of Commons has tended to cross-question civil servants, and even to some extent the heads of research councils — even though the witnesses sometimes feel they are not revealing vast knowledge — will only work effectively if scientists are willing to make themselves available to the political community. I would criticise scientists in Britain by saying that, in general, they have not been all that readily available, and have been a bit suspicious of people taking time off from the lab to talk to "those amateurs out there". I think that's rather a mistake.

DD: You have frequently suggested that there should be more of a scientific lobby. Do you feel there has been any movement in this direction?

SW: A little. The research councils, and particularly the heads of the research councils, have done much more to come out and explain what they are doing. And insofar as the barriers between the sciences are beginning to break down — for example through joint research projects between the different councils — as well as to some extent the barriers between the scientists and the press, then the research councils are pushing in the right direction.

DD: But once money begins to get tight, are you not required to make a better case justifying support?.

SW: Yes, and I think that's right. One parallel that has always struck me forcefully is that you could increase the arts budget by 15%, and the entire arts lobby would shout its head off about how mean it was, because they always want at least 25% increase a year. But if you increase the science budget by 5% in real terms — say 11 or 12% in money terms — scientists would always be rather grateful. Now I think that the arts lobby overdid it, but they have a large lobby of people who will write letters to the newspapers, speak in the House of Lords, and so on. The scientists — who, thank goodness, are at long last beginning to appear in the Houses of Parliament — are not so ready, don't react so quickly, don't fight so hard. I wouldn't want to push it so far as the arts lobby does, which may even be slightly counterproductive, but I still think there is something to be said for closing the gap a bit.

0028-0836/80/0008-02$01.00

DD: How do you feel about the way that concerns about the social impacts of science have been institutionalised — the Genetic Manipulation Advisory Group is the obvious example — and of the way that the scientific community has responded.

SW: There have been many types of responses. GMAG is only one example, and indeed the fact that the Association of Scientific, Technical and Managerial Staffs recently held a conference on GMAG is a good example of how questions about the social impacts of science have been spread beyond the small community of scientists and administrators that directly interweave with them. The Windscale Inquiry is another good example, which was rather well handled, if one compares it with some of the tremendous clashes that there have been in France and Germany. The whole idea of having an inquiry of that kind, with a judge in charge, but passing the conclusions on to the House of Commons for a free vote, was rather an innovative way of going about an area where science and social policy come up against one another.

One example where this went badly was in the area of dangerous pathogens — the smallpox case at the Univeristy of Birmingham; and that was because the dangerous pathogens' rules and regulations pre-date public interest in the field of science and social policy, so that what we had was a relatively secretive and relatively unpublicised system of control and regulation. Immediately something went wrong, the Shooter Report on the smallpox case was able to pinpoint all sorts of holes in the system, because it hadn't really been looked at. People had become complacent about it; it wasn't within the light of the public domain. GMAG was; nuclear power to some extent is, although I would like to see a broader range of public interest brought in; and this is also particularly true in the area of advanced medical science.

As for GMAG, as a device for meeting public concern and, in the initial stages, for allowing experiments to be conducted in closely controlled situations, it had a great deal to be said for it. As a step into a whole new area of science with a great number of public fears associated with it, you only needed to have one accident for the whole of genetic engineering to be at great risk, and for some parliamentarians to say "ban the lot". Indeed there was quite a strong move in Parliament to say that we should not do some of the experiments that fell into the containment categories. And so although I know now that some scientists, and even more industrialists, would criticise GMAG as being exceptionally restrictive, nevertheless as a way of showing that public fears were being taken seriously it was an important beginning. The risks may be low; but what's at stake is so high that the risk-benefit equation does involve a great deal.

What bothers me about the US is that the controls and regulations, such as they have been — I use that tense advisedly — do not really extend very much into the private sector. And, of course, there are countries, such as Switzerland, where the private sector is relatively unregulated. Given that what we are looking at should be an international system of regulation — you can erect national systems, but what difference does that make to a virus? — one has to make some sort of a compromise. I realise that it would almost certainly not be as rigorous as the current GMAG rules to be widely acceptable, but one hopes it would have rather more sensible safeguards, especially with regards to category III and category IV experiments. Britain might have a more regulated national system than some other countries; but the general principles of good practice at the bottom end and pretty strict regulation at the top end is something we ought to try to get across through the European Science Foundation, and in other ways.

DD: The US is currently experiencing a political reaction against regulation, and is caught in the trap while move is being learnt about potential environmental and health hazards, the less regulation becomes politically acceptable. How do you correlate social and political needs?

SW: The way I see it, the US often needs regulation to help make sense of its legislation, which has often been cast in the form that will generate sufficient support — legislation emerging from a process of creating a coalition to get it through. Regulation then becomes the way that you rationalise this rather strange cross-path of legislation. If one takes the fields of education or employment — or for that matter safety and health — one finds that the regulations are extremely detailed and precise, but that they are often changed and amended in the light of events. So that you find people responsible for regulation almost going round the bend with the sheer weight, change and detail of the regulation. And that, in turn, leads to the kind of antithesis of people like Senator Edward Kennedy, for all that he is a liberal senator, moving against regulation.

DD: How do you see the future prospects for science in Britain? What are the new political pressures likely to be in the 1980s?

SW: One important need is for the leaders of the scientific community to get across the idea of lead-times; in other words, to try to get agreement as far as possible that a substantial chunk of the budget ought, as far as possible, to be insulated from year-to-year changes. I'd like to see the budget split between extra money that could be used quickly, and money which requires to be committed for some time, since one of the most difficult things to do is to set up a team of people and then to discover a year or two later that the team is chopped off from its funds, or from half of its funds, just when it is getting going.

Secondly it is important to move in the direction that Geoffrey Allen of the SRC talks about, namely providing fellowships on a four- or five-year basis for young scientists. I am very concerned that the profile of the academic world is such that unless we are very careful, some of the most able of the new generation of young scientists will not get jobs in universities.

DD: But looking at the question the other way round, what new challenges can you see science having to face from the political body — or from the social body — to which it will have to respond?

SW: One area in which a great deal of thought is needed is the extent to which the 'sophistication factor' is likely to have an impact on certain major areas of public finance, particularly in health. A scientist once said to me that if heart transplants had been generally successful, the National Health Service would be in even more trouble than it is, and that seems to me correct. We should be worrying whether the sophistication factor, particularly in medicine, will in practice mean that one is budgeting against the needs of the great majority of the population. It is extremely important to notice how anti-distributive the effects of advanced medical technology can be. Look at the US where medicine has become so expensive because of the technology that, in practice reasonably decent intermediate technology medicine is out of the range of part of the population.

I believe that the government — particularly people concerned with the health field, though pensions and mental health also come into this — should decide, together with scientists, what profile of research is likely to ease the position of hard-pressed health budgets, and what research is likely to make it worse.

People should be aware of the costs as well as the benefits of successful research. Even in the US, in the discussions that I have followed here on medical insurance schemes, almost nobody has taken up the theme of the massive consequences of rapidly advancing medical technology in terms of health care. If I can be blunt, I think that in ten years time it will be impossible to finance any effective public medical service in the US, because a great range of less expensive but reasonably effective technologies will have been ruled out.

DD: Does this mean you see the science budget more and more closely linked to other areas of government spending and social policy? How can the social impact issues be brought into the policy process?

SW: I think that it has to be done at every level. Certainly the research councils should take such matters into consideration. But one would also have to have a kind of parallel system, parallel meetings of interest groups in the House of Commons and in the mass media. This would mean the scientific community being brought together with economists and social scientists more often to look at the implications of certain advances. ☐

CORRESPONDENCE

Indian science fails to meet basic needs of the country

Sɪʀ, — Anil Agarwal's article on 'Indian Science' brought out several interesting points. However, he has failed to raise some basic issues. For example, while India is spending money for highly sophisticated technology such as space and nuclear research, science and technology, even in their crudest form, have not reached the mass of Indian villagers, for whom hunger and starvation are an everyday reality. Indian science policy was not able to prevent the Bihar famine and recent floods and cyclone disasters. It has, however, led to the creation of bureaucratic research institutions and to the mushroom growth of CSIR research laboratories. It is, in fact, only the continuation of a policy which existed in colonial times. Research institutions such as CSIR, the Atomic Energy Commission and the Defence Research Laboratories are prestige institutions. Most Government bodies are bureaucratic institutions controlled by a few individuals.

India has built up a sizeable infrastructure for research and industry, but technology for manufacturing common household goods, such as dry batteries or condensed milk, still has to be imported. Indian scientists have given no thought to the need of basic technology in their country. Despite the green revolution, agricultural wages have declined or stagnated in real terms. The population of cities is increasing annually by about 5% because of the influx of the impoverished from the countryside.

The present attempts to formulate a science policy do not account well enough for education. The type of science education given in Indian universities is imported from western countries, and has no relevance to Indian society. A large amount of money has been spent on universities, research institutions and engineering colleges. At the moment there are more than 3,000,000 students in universities, more than one third of them being science students. By the end of 1979 the figure will rise to more than 5,000,000.

Indian universities have become factories for producing graduates. But why expand like this when there are not enough jobs for those who already have degrees? Recently there were more than 40,000 applicants for 40 vacancies; and for a few vacancies in nationalised banks there were so many applications that they had to be collected in vanloads. Unemployment among graduates runs at more than 30% and in large cities the situation is really alarming. Even though most universities provide undergraduate science and technology courses, the standard is pretty bad. That of science teaching in private colleges (which are affiliated to the universities but run on a commercial basis) is far below normal. Most teachers do not have sufficient qualifications to teach at this level and laboratory facilities are very bad.

What is the point of producing graduates who do not come up to reasonable standards and who do not serve any useful purpose in Indian society? Instead, science education should aim to teach basic ideas on a *mass scale*. The standard of science teaching in schools must be improved before talking about undergraduate study. Most schools in small towns have to be content with spirit lamps, and experiments are not devised to make maximum use of existing facilities.

It would, for example, be a good idea to use experimental kits (like those devised by the Open University) which could be stored in small towns, each store forming the nucleus of a science centre. Mobile service units, manned by trained teachers and operating from those centres, could go to villages and explain to children, with the help of simple experiments, the concepts of basic science and technology. So far Indian science education has no relevance to Indian society.

Although a lot of noise has been made in favour of appropriate technology, it has failed to make any impact on rural development in India. This is because appropriate technology by definition is an indigeneous self-generating process arising as a response to the economic and social needs of various forms and levels of society instigated and initiated by the users of existing technology. Such technologies will not work satisfactorily until farmers have experienced the benefits of communal production and projects and are thus able to design and operate such equipment. Unless the desire for change and for an appreciably higher standard of living takes place in the peasant communities (which is happening among Punjab and Hariyana farmers) new techniques will not be accepted or exploited fully.

At present the keystone of Indian science education is elitism and personal achievement rather than social responsibility; centralisation rather than dispersion; urban rather than rural development; consumption rather than aesthetic development. What is important and essential is that basic science and technology should be oriented towards the needs of the Indian society. Above all, the masses must be carried with technological development and not isolated from it.

Yours faithfully,

A. Vᴀɪᴅʏᴀɴᴀᴛʜᴀɴ

Nuclear secrets

Sɪʀ,—We concur with the sentiment expressed in your editorial *Nuclear secrets: no clear frontiers* (18 October page 511) that the "narrower question of American security should yield to the broader one of global non-proliferation". But we hope you did not mean that articles about hydrogen bombs should not be published simply because of "sincerely held views" that such articles contribute to proliferation.

Neither of the disputed documents could be of aid to a state in the initial acquisition of nuclear weapons, because the documents discuss thermonuclear weapons, for which a fission weapon capability is a prerequisite. Moreover, most of the dialogue and court proceedings *was* in the broader context of global non-proliferation.

Months ago, before the temporary restraining order was issued by Judge Warren, we technically reviewed Morland's article for *The Progressive*. The article and letter do not contain design details; rather they discuss various — oftentimes incorrectly applied — concepts already known to scientists throughout the world. It is therefore difficult to understand how such an article can further affect the already precarious international situation we now face.

Technical information is essential to informed political debate on an enormous range of issues. For example, thinking only of current policy debate concerning nuclear weapons and nuclear arms limitation, we might list the following: the SALT treaty, the necessity of the MX missile, its siting alternatives, and a comprehensive nuclear test ban.

The US and other nuclear weapons-states must face the fact that five nations, without help, have successfully undertaken the industrial and scientific effort necessary to make hydrogen bombs. The average length of time to achieve a fusion explosion has been five years after first testing a fission device. That this average was as long as five years is more likely due to political indecision and industrial development time rather than a lack of understanding of elementary concepts.

Motivation and resources are far more important determinants than underlying concepts. It is still prudent for governments to avoid authenticating (through their powers of classification) partially correct public information, such as the Morland article and various letters. But mainly they should concentrate on protecting their own ultrasensitive official documents containing weapons-design data, for example UCRL-4725 and -5280, which the US Government erred in making available to the public.

The issues involved in the case go far beyond the question of weapons data alone. For example, the US Government in its brief to the 7th Circuit Court of Appeals in Chicago raised the argument that "technical data" are not constitutionally protected under the First Amendment because they are not an "essential part of any exposition of ideas" and are not of any "social value as a step to truth". In a world as technologically oriented as ours, such an argument is not only nonsensical and false, it is dangerous to the functioning of free societies.

One of the issues raised by Morland is that unnecessary secrecy can tranquillize public debate. Partly because of reliance on technology-denial and secrecy, several US Administrations have avoided a moratorium on testing, production, or deployment of nuclear weapons — although such restraint would retard proliferation far more substantially than does the illusion of security through technology-denial and secrecy. The most urgent need is a universal nuclear test ban, which might be introduced as an amendment to the Nuclear Non-Proliferation Treaty.

All of the signatories to this letter are engineering physicists who have filed affidavits regarding the various letters and articles relevant to *The Progressive* case and two of us have had access to the classified and "in camera" documents. This letter has no official connection with the Argonne National Laboratory, with the University of Chicago, nor with the UK Department of Energy.

Exposing sociobiology?

Sɪʀ,—I am pleased to detect a slight shift in *Nature's* editorial predilections, from totalitarian socialism to totalitarian Mahometism. At least, as Mr Crouchback would say, they have a king and some sort of religion.

Perhaps you will now find it possible to expose the sociobiological theories as no mereappendage of Naziism, but the very emanation of Satan; whose hand can now be discerned — in the horrific decline in spirituality — to say nothing of the savage cuts in public expenditure, and insecurity of tenure in medical research jobs — that has plagued the West since the Turk was stopped at the gates of Vienna.

Your faithfully,

Cʜᴀʀʟᴇs W. Cʟᴀʀᴋ

A new twist for DNA?

from David R. Davies and Steven Zimmerman

IN the twenty-seven years since Watson and Crick proposed that B-DNA is a right-handed double helix, the concept of a regular DNA structure, varying only in the chemical sequence of its bases, has become one of the foundations of molecular biology. Although fibre diffraction of DNA shows the existence of at least three distinct forms, thereby demonstrating the flexible nature of the sugar phosphate backbone, the structure in solution has always been believed to be a regular B form. Occasionally, suggestions have been made that some DNAs, particularly with unusual base sequences, could adopt significantly different conformations, but the evidence has never been conclusive.

This situation has recently changed dramatically. There are now two clear examples, both deoxypolymers with simple alternating sequences, for which strong evidence exists that the conformation of the backbone in solution is also alternating. In one case, poly(dA–dT)·poly(dA–dT), the current model is still a right-handed double helix similar to B-DNA in general form. For poly (dG–dC)·poly(dG–dC), on the other hand, a remarkable left-handed structure has been proposed by Wang *et al.* (*Nature,* **282,** 680; 1979) on the basis of the elucidation of the crystal structure of the hexanucleotide $d(C-G)_3$. In this crystal two molecules are combined with Watson-Crick base pairing to form a double helical segment with remarkable internal regularity. In addition, neighbouring segments pack on top of one another to approximate an infinite helix with antiparallel strands and twelve base pairs per turn. This structure has been termed 'Z-DNA'.

In this new Z helix the conformations of the guanine and cytosine deoxynucleotides differ considerably from one another so that the repeating unit becomes a dinucleotide, unlike the B-DNA helix in which the repeating unit is a single nucleotide. The torsion angles of the bases relative to the sugars are quite different. Whereas the cytosine adopts the *anti* conformation relative to its deoxyribose as in B-DNA, the guanine adopts the *syn* conformation. The puckers of the two deoxyribose rings are also different, being C3′ endo for two internal deoxyguanosines and C2′ endo for the deoxycytidines. Finally, the conformation of the backbone about the C4′-C5′ bond is *gauche-trans* for the dG residues and *gauche-gauche* for dC. The net result of these differences between the purine and pyrimidine nucleotide conformations is to produce a staggered zig-zag course for the deoxyribose phosphate backbone, hence 'Z-DNA'.

David R. Davies and Steven Zimmerman are in the Laboratory of Molecular Biology, National Institute of Arthritis, Metabolism and Digestive Diseases, National Institutes of Health, Bethesda, Maryland.

These single crystal results imply strongly that this hexanucleotide structure could exist in a polymer of deoxynucleotides. Indeed, Arnott *et al.* (*Nature* in the press) have now observed a form of poly(dG–dC)·poly(dG–dC) that they believe from X-ray fibre analysis to be the Z-form. The helical parameters of this fibre pattern show a remarkable correspondence to those of the crystal. The former have a helical pitch of 43.5 Å with 12 base pairs, compared with the prediction from the crystal of 44.6 Å. The fibre also provides evidence for a dinucleotide repeating unit.

Arnott *et al.* (*op. cit.*) have observed that the same fibres that initially gave B-form diffraction patterns later gave Z-form patterns. This implies that the molecules can undergo a change of direction of the helix twist within the fibre in a relatively confined space without greatly altering the orientation of the double helices and without getting significantly tangled. Wang *et al.* (*op. cit.*) point out that the transformation between Z and B will involve separation of the base pairs, a large rotation of the guanine base accompanied by a rotation of the entire deoxycytidine residue, followed by rejoining of the base pairs. They note that the junction between Z and B-DNA will have a stacking discontinuity which might result in a kink in the molecule.

There is evidence that the Z-DNA conformation is not restricted to poly (dG–dC)·poly(dG–dC). Arnott *et al.* report the observation of this form in fibres of poly(dG–dT)·poly(dA–dC). They also interpret the X-ray diffraction results of Saenger *et al.* (*Jerusalem Symposium on Quantum Chemistry and Biochemistry* **V,** 457; 1973) for the alternating copolymer of deoxyadenylate and 4-thiothymidylate in terms of a modified Z helix with 14 base pairs in a pitch of 54 Å.

The anomalous behaviour of poly (dG–dC)·poly(dG–dC) has been known for some time. Pohl and Jovin (*J. molec. Biol.* **67,** 375; 1972) were the first to observe two distinct forms of poly(dG–dC)·poly (dG–dC) in solution, with a cooperative transition occurring between them at high salt concentrations. The circular dichroism spectrum of the high salt form is nearly an inversion of that of the low salt form, which in turn resembles that of B-DNA. This suggests that the transition to the high salt form involves a rearrangement of the bases. Wang *et al.* (*op. cit.*) believe that their Z-form corresponds to the high salt form, even though the $d(C-G)_3$ was crystallised at relatively low salt concentrations. This interpretation is consistent with the results of a previous NMR investigation of $(dG-dC)_8$ by Patel *et al.* (*Proc. natn. Acad. Sci. U.S.A.* **74,** 2508; 1979), who clearly demonstrated that the repeating unit in the high salt structure is a dinucleotide, and that marked differences between the two phosphodiester linkages (that is, dCpG and dGpC) give rise to two peaks in the high salt ^{31}P NMR spectrum. Differences in the sugar hydrogen resonances of the two forms also led to a prediction of a dramatic change in either the guanosine or cytidine glycosidic torsion angle during the transition from the low to high salt form.

How do these results relate to the 'alternating B-DNA' model recently proposed for poly(dA–dT)·poly(dA–dT), (Klug *et al. J. molec. Biol.* **131,** 669; 1979)? This model is based on the crystal structure of the tetranucleotide $d(A-T)_2$ (Viswamitra *et al. Nature* **273,** 687; 1978) which also has different nucleotide conformations, with the thymidine sugars in the C2′ endo conformation while the deoxyadenosine sugars are C3′ endo; in addition the O–P torsion angles are *gauche gauche* for the dA(3′5′)dT segments and *trans gauche* for dT(3′5′)dA. Klug *et al.* used this result as the basis for a hypothetical 'alternating B-DNA' structure for polynucleotide sequences containing alternating purines and pyrimidines. Although it has an alternating backbone, this structure is closely related to B-DNA and is quite different from Z-DNA. The NMR analysis of fragments

0028-0836/80/0011-02$01.00

of poly(dA–dT)·poly(dA–dT) 145 base pairs long supports the concept of an alternating backbone conformation with a dinucleotide repeat, the ^{31}P resonance showing a small splitting (Shindo *et al. J. biol. Chem.* **254**, 8125; 1979). Also, in a joint X-ray/NMR study on fibres of poly(dA–dT)·poly(dA–dT), (Shindo & Zimmerman, *Nature* in the press) calculated NMR resonances that are consistent with the 'alternating B-DNA' model of Klug *et al.* As the 'alternating B-DNA' structure was also anticipated to occur for poly (dG–dC)·poly(dG–dC), it is surprising that the low salt form of this polymer shows no splitting of the ^{31}P resonance.

We should point out that the various models that have been proposed for left-handed or side-by-side DNA of irregular sequence (references may be found in Crick *et al. J. molec. Biol.* **129**, 449; 1979; *News & Views* **278**, 780; 1979) are quite different from Z-DNA and from the alternating B-DNA structure, both of which seem to be a response to a regular purine–pyrimidine alternating sequence.

Is the left-handed Z-form likely to be found in DNA *in vivo*? Where there are stretches of alternating GC sequence (or possibly even some other kinds of alternating purine–pyrimidine sequences), the potential will exist for forming this structure. However, the transition from B to Z occurs at the rather unphysiological salt concentrations of 2.5 M NaCl or 0.7 M MgCl$_2$ (Pohl & Jovin *op. cit.*) which might seem to make the Z-form unlikely except in halophiles; nevertheless, complex ions such as polyamines or specific binding proteins might favour the transition. It is interesting that the association of complementary closed circular single-stranded DNA molecules can occur over as much as 70% of the length of each DNA strand (Stettler *et al. J. molec. Biol.* **131**, 21; 1979). Topological considerations and the observed circular dichroism changes suggest that some segments of this DNA are left-handed but the extent, regularity and conformation of these segments are not known. If left-handed helical regions do occur in DNA *in vivo*, they might be associated with significant biological effects through their interactions with DNA-specific enzymes and binding proteins. Also, the presence of the Z-conformation in supercoiled DNA would influence the interpretations of supercoiling. It has been suggested by Gellert and Mizuuchi that the energy stored in supercoiled DNA might cause appropriate alternating sequences to snap over into the Z form even at physiological salt concentrations. On the basis of the detailed structural information now becoming available, experiments can be designed to test these possibilities. ☐

Quick-freezing — the new frontier in freeze-fracture

from David Shotton

A TECHNIQUE for the ultrastructural preservation (fixation) of biological specimens by extremely rapid freezing in the absence of cryoprotectants has been developed for freeze-fracture and thin-section electron microscopy by John Heuser (of the Department of Physiology at the University of California Medical School in San Francisco) and Thomas Reese (of the National Institute of Neurological and Communicative Disorders and Stroke, at the National Institutes of Health in Bethesda). This promises to open a new chapter in biological ultrastructure research, because it now makes possible electron microscopic studies of biological events which occur within the millisecond time range, permits the observation after freeze-etching of surface features previously obscured by non-volatile chemical cryoprotectants, and allows a critical evaluation to be made of the artefacts produced in biological specimens by the chemical fixation and cryoprotection techniques routinely used by electron microscopists.

Results which Heuser, Reese and their colleagues have obtained by using the quick-freezing technique on three distinct biological systems have recently been published in three beautifully-illustrated papers contained in the latest volumes of the *Journal of Cell Biology* (Heuser *et al. J. Cell Biol.* **81**, 275; 1979; Heuser & Salpeter *J. Cell Biol.* **82**, 150; 1979; Chandler & Heuser *J. Cell Biol.* **83**, 91; 1979), giving us a chance to assess the significance of this development.

In essence the technique is very simple, and involves bringing a biological specimen, fixed beneath the lower end of a vertical falling rod, rapidly into firm contact with the upper polished surface of a pure copper block cooled from below to approximately 4 K (–269°C) with liquid helium. Their first quick-freezing machine, described by Heuser, Reese and Landis in 1976 (*Cold Spring Harbor Symp. quant. Biol.* **40**, 17), was developed from the design originally put forward in 1964 by Van Harreveld and Crowell (*Anat. Rec.* **149**, 381; Van Harreveld *et al. J. Cell Biol.* **25**, 117; 1965). It resembled in principle the simple liquid nitrogen-cooled copper block freezing method of Dempsey and Bullivant (*J. Microscopy* **106**, 251; 1976), although it had the important advantages of automation, a colder initial block temperature and a sophisticated specimen mounting system which minimised contact damage.

An improved version of their apparatus is now described by Heuser *et al.* (*op. cit.* 1979). With it they could freeze the surface 10 μm layer of living specimens within 2 ms, with excellent ultrastructural preservation and minimal ice crystal damage. Further from the surface, the inherently low thermal conductivity of biological tissue limited the rate of heat loss and unavoidably led to the growth of large ice crystals and consequent tissue damage, similar to that observed whenever tissue is frozen without previous chemical cryoprotection by conventional techniques of immersion into freezing Freon-22 or nitrogen slush.

Once frozen by the quick-freeze method, specimens can either be freeze-fractured and replicated in the normal way, care being taken to ensure that the fracture plane passes through the surface 10 μm layer, or alternatively can be freeze-substituted and chemically fixed at –95 °C in a thawing acetone-osmium tetroxide mixture before embedding for thin-section electron microscopy. One particular advantage of this copper block quick-freezing method over liquid propane jet-freezing methods, which also give improved rates of cooling, is that the well-frozen layer of the specimen is physically flat and parallel to the specimen support, enabling extensive freeze-fracture replicas from this region to be obtained using a Balzers microtome system.

The most important and exciting advantage of this quick-freezing method, in comparison with conventional ultrastructural approaches, is that it enables living specimens to be instantaneously frozen with good ultrastructural preservation at known intervals after a biological stimulus, and so makes it possible to use the electron microscope for kinetic studies of transient biological events which are completed within a few seconds or even, with certain favourable specimens, within a few milliseconds. It was for this purpose — to visualise the train of events which occurs at the presynaptic membrane of the frog neuromuscular junction during the first few milliseconds after the arrival of a nerve impulse — that Heuser and Reese originally developed their apparatus. The results they obtained are presented in the papers by Heuser *et al.* (1976 and 1979, *op. cit.*) and Heuser *Soc. Neurosci. Symp.* **2**, 215; 1977), and a further paper now in press.

Living cutaneous pectoris muscles were dissected intact from frogs, with their motor nerve attached. Each thin sheet-like muscle was individually mounted onto the specimen support of the quick-freezing machine, and was caused to contract by

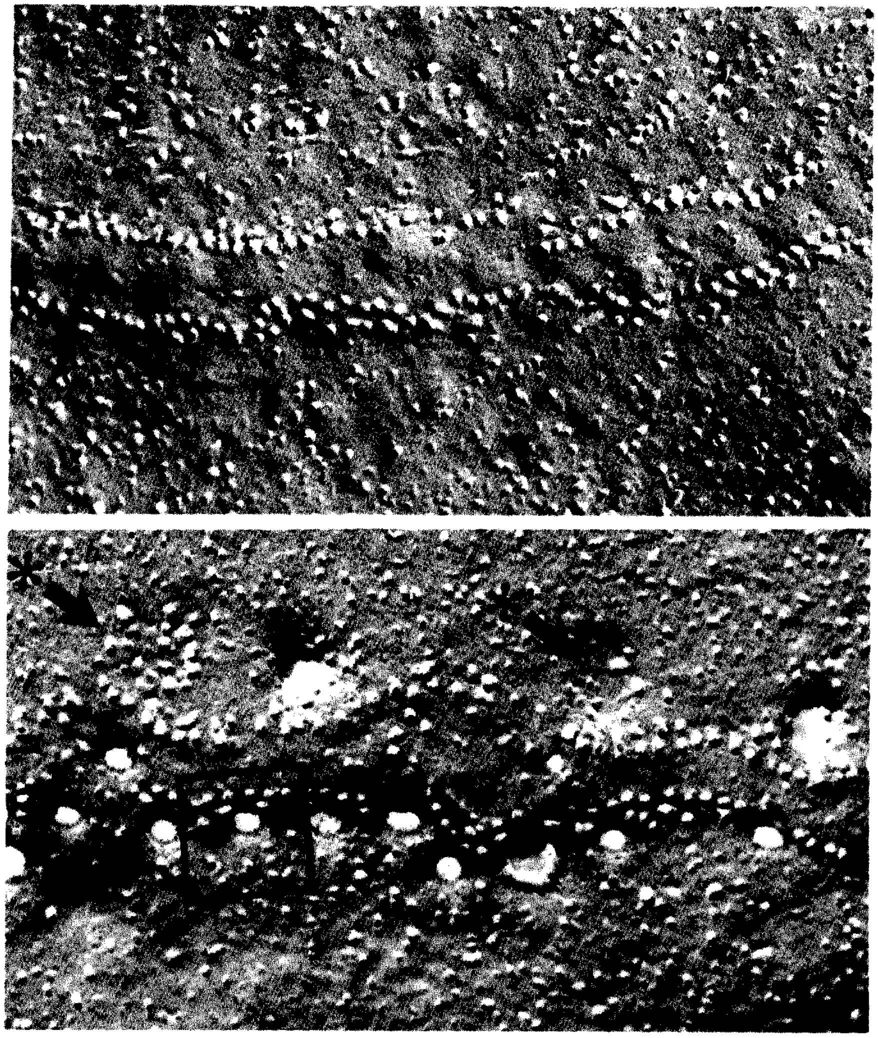

Fig. 1 *a*, High magnification view of the 'P face' of one active zone from a frog motor nerve terminal soaked in 1 mM 4-AP and 10 mM Ca^{2+} for 30 min and given one stimulus 3 ms before freezing. By 3 ms, the action potential presumably arrived in the terminal, but it did not alter the resting appearance of the active zone, which is recognised as a slight ridge bordered by parallel rows of large intramembrane particles. × 143,000. *b*, P-face view of an active zone from a nerve terminal treated like the one in 1*a*, but given one nerve stimulus 5 ms before freezing. In the interval between 3 and 5 ms, just at the time when the nerve begins to discharge large numbers of acetylcholine quanta, many membrane perturbations appear along the edges of the active zone. These are believed to be exocytotic stomata, or openings into the underlying synaptic vesicles. The two areas marked by asterisks are thought to be vesicles that have collapsed flat after opening; they display a telltale cluster of two or more large intramembrane particles like those found in intact synaptic vesicle membranes. The square encloses an early stage in one characteristic exocytosis event.

electrical stimulation of the nerve as it fell towards the cold copper block. The interval between the arrival of the nerve impulse at the neuromuscular junction and the moment at which the specimen froze solid was recorded on an oscilloscope, and was later related to the appearance of the presynaptic membrane after that specimen had been freeze-fractured, enabling the investigators to determine the time course of the exocytotic events caused by the fusion of the synaptic vesicles with the presynaptic membrane. 4-aminopyridine (4-AP) was used to increase the number of acetylcholine neurotransmiter quanta discharged with the arrival of each nerve impulse from the normal level of less than one quantum per presynaptic active zone of transmitter release to a level at which they could more easily be studied. No structural changes were observed during the first 3 ms after stimulation (Fig. 1*a*), but by 5 ms narrow exocytotic openings were visible at fusion sites all along the active zones (Fig. 1*b*). During the subsequent 20 ms, these fused vesicle membranes collapsed and flattened out, leaving only faint depressions in the postsynaptic membrane, each containing two or more particularly large intramembrane particles not previously present on the presynaptic membrane. The subsequent fate of the vesicle membrane components thus inserted into the presynaptic membrane was followed by quantifying the movement of these large intramembrane particles over the next 400 ms, during which period they moved away from the active zones towards sites of coated vesicle endocytosis, in the region between adjacent active zones.

The ability to undertake such direct kinetic studies represents a significant breakthrough in cell biology, since in the past kinetic sequences of rapid events at the ultrastructural level could only be deduced from static electron micrographs of chemically-fixed specimens, arranged into postulated temporal sequences on the basis of the investigator's preconceptions of what might reasonably be expected to occur. For neurobiology in particular, these studies provide further strong direct support for the synaptic vesicle fusion and recycling scheme first proposed by Heuser and Reese in 1973 (*J. Cell Biol.* **57**, 315).

The second advantage of quick-freezing is that, by being able to freeze delicate biological specimens from dilute aqueous solutions in the absence of chemical cryoprotectants without ice crystal damage, one can then expose the outer surfaces of membrane, extracellular structures and intracellular cytoskeletal elements by freeze-etching, a technique in which water molecules are allowed to sublime from the frozen surface of the fractured specimen before replication. In the past this technique could only be applied with any degree of success to rather sturdy small cells in suspension, such as erythrocytes, yeast and bacteria, which could withstand conventional freezing procedures without cryoprotection.

Heuser and Salpeter (1979 *op. cit.*) have studied unprotected quick-frozen postsynaptic membranes from the electric organs of the electric rays *Torpedo californica* and *Narcine brogiliensis* in this way. Besides giving us fascinating views of the structure of the basal lamina within the synaptic cleft, of intracellular cytoskeletal filaments and of synaptic vesicles, they have revealed that the acetylcholine receptor molecules form striking extensive ordered arrays, which can be seen not only as protrusions on the etched external surface of the postsynaptic membrane (Fig. 2*a*), resembling those previously reported on etched *Torpedo* membrane vesicles by Cartaud and his colleagues (*FEBS Lett.* **33**, 109; 1973; *Proc. 6th European Congress on Electron Microscopy, Jerusalem*, 336; 1976; *J. Cell Sci.* **29**, 313; 1978) but also as low-profile particles on the E fracture face of these unfixed quick-frozen membranes (Fig. 2*b*). Orci, Perelet and Dunant (*Proc. natn. Acad. Sci. U.S.A.* **71**, 307; 1974) had previously obtained limited views of such E-face particle arrays, but in others' hands they have usually been rendered invisible by artefactual changes resulting from glutaraldehye fixation and glycerination. They occur at a density (>10,000 μm^{-2}) which correlates well with previous physiological and autoradiographic estimates of the receptor packing density. This density is much higher than that of the larger intramembrane particles seen on the fracture faces of both fixed and unfixed membranes, which had often previously been assumed to represent the receptor molecules.

The third advantage of the quick-freezing method is that it enables one to evaluate the artefacts produced in biological specimens by the alternative chemical fixation and cryoprotection techniques normally used by electron microscopists. One example of this, from the work of Heuser and Salpeter, is the striking differences in appearance and aggregation state of the intramembrane particles on the P and E fracture faces of *Torpedo* postsynaptic membranes when freeze-fractured after quick-freezing and after glutaraldehyde fixation, glycerination and Freon freezing. Other examples of such artefacts, which are important in assessing current theories of membrane fusion, come from the studies which Chandler and Heuser (*op. cit.* 1979) have made of cortical granule exocytosis in fertilised sea urchin eggs. In this work, the authors used the quick-freeze technique to capture stages in the 'cortical reaction' which originates from the point of entry of the sperm and which within 30 s sweeps across the entire surface of the egg. This process starts with the explosive exocytosis of the cortical granules, causing the characteristic elevation of the vitelline layer, and is followed by an elaboration of microvilli and subsequent membrane recovery by coated vesicle endocytosis. Chandler and Heuser found that freeze-fracture replicas of eggs fixed with glutaraldehyde and cryoprotected with glycerol before freezing displayed forms of interaction between the granule membrane and the plasma membrane, including particle-free single-bilayer membrane diaphragms formed from apposed fusing membranes, which looked identical to those described by other investigators and proposed as essential intermediates in the process of membrane fusion (see *News and Views* **272,** 16; 1978). However such membrane interactions were never found in eggs which had been quick-frozen without glycerination, even after glutaraldehyde fixation. The authors review other recent literature reporting lability of aldehyde-fixed membranes and glycerol-induced membrane changes, and conclude that many of the postulated 'intermediate stages' in fusion are in fact artefacts resulting from the lack of complete stabilisation of lipid bilayers by aldehyde fixation, exacerbated by the dehydrating effects of glycerol. This is further discussed by Chandler in a forthcoming book entitled *Freeze-fracture: Methods, Artifacts and Interpretations* (eds Rash & Hudson, Raven Press, New York). Since glutaraldehyde does not affect most membrane lipids, such lability is not unreasonable, but the question remains as to what chemical changes have already occurred in those membranes to permit such artefacts to develop only in situations where membrane fusion is imminently likely to occur.

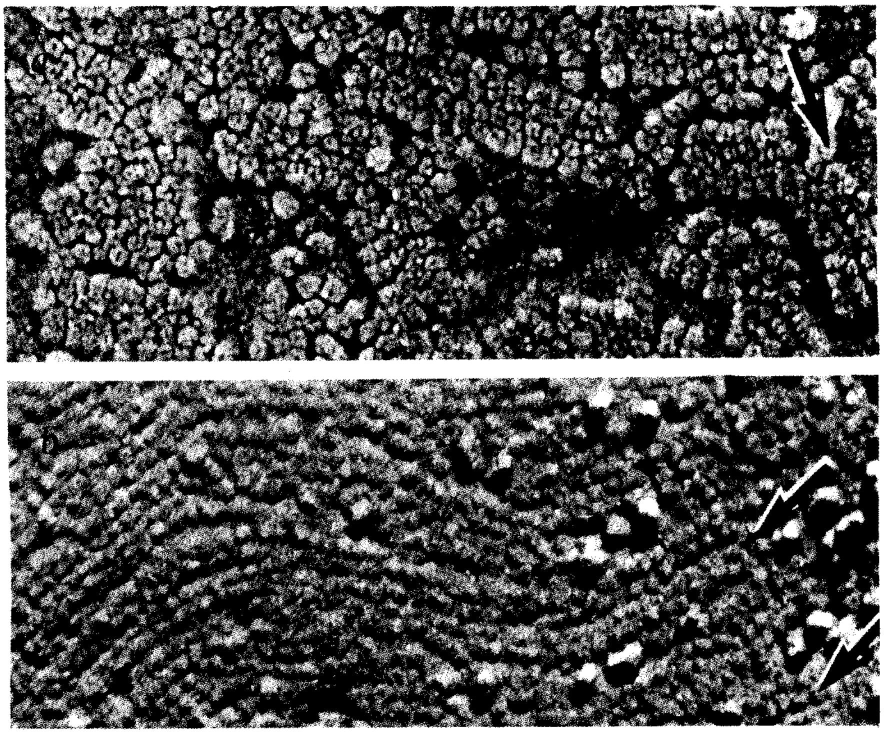

Fig. 2 *a,* Characteristic view of the pattern of grouping of surface projections seen on deep-etched postsynaptic membrane fragments. The most obvious pattern is rows four abreast, with many breaks and curves (arrow). × 270,000; so 3 mm ≃ 10 nm. *b,* Unidirectional shadow-casting of an unetched E face of the postsynaptic membrane, exposed by fracturing intact, quick-frozen tissue, which illustrates that the shallow bumps seen on this surface also group into curvilinear rows, most often two or four abreast (arrows), like the surface projections in Fig. 2a × 270,000; so 3 mm ≃ 10 nm.

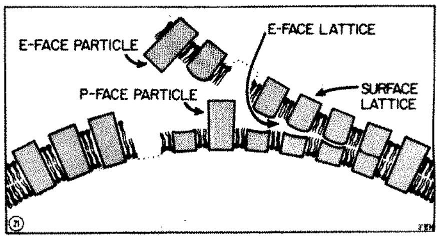

Fig. 3 Diagram illustrating, first, how cleavage of intramembrane receptor molecules could generate the match between the E face lattice and the surface lattice of projections that is observed in etched *Torpedo* post-synaptic membrane; and second, how extraction of whole receptors from one leaflet or the other could generate the large intramembrane particles which also characterise this membrane.

The quick-freezing method instantaneously samples one particular moment in a biological process, and avoids the accumulation of intermediate stages which sometimes happens during slow death aldehyde fixation. As Chandler and Heuser were not able to detect preliminary fusion stages in their quick-frozen fertilised eggs, before seeing fused granules open to the extracellular space, they concluded that such stages could last no longer than 5 ms. An understanding of the molecular events which initiate membrane fusion thus seems as elusive as ever! ☐

100 years ago

The *Hannoversche Courier* announces that Leibnitz's long-lost calculating machine has been recovered. Leibnitz invented and constructed this machine in 1672, during his stay in Paris. It can add, subtract, divide and multiply and was the wonder of the time. This machine became the property of the Hanover public library, but long ago disappeared from among its treasures. All that was known about its disappearance was that it had once been sent to an instrument maker at Göttingen to be repaired. It has now turned up again in the Göttingen library.

It is only about a year since we gave some account (Nature, vol. xviii. p. 361) of the railway bridge which spans the Firth of Tay at Dundee, and on Sunday it was the scene of one of the most terrible railway accidents on record. With the details of this sad occurrence our readers are no doubt familiar; for accurate information as to the prime cause we must await the searching inquiry which will no doubt be instituted. The structure appears to have been subjected to the most rigid tests before being opened to traffic, but we fear there must have been more than one screw loose somewhere. Upwards of 3,000 feet of the high girders are reported to have been swept away. One conjecture is that the train had got well upon the girders when a gust of greater strength had caught the structure. There would thus be, in addition to the ordinary vibration of the train, an enormous lateral pressure from the wind.

The great mouse festival

from R.J. Berry

To most people the house mouse is a commensal nuisance; to many biologists it is a necessary research tool, bought off the shelf (as it were) in the same way as a chemical. Yet the mouse is a real animal, approved because "its fertility, prolificity, convenient size, short gestation period, its manifold variations, inexpensive maintenance, resistance to open infections, susceptibility to certain diseases, and ease of production conspire to make it the laboratory animal par excellence". So wrote Clyde Keeler in 1931. Ten years later, L.C. Strong was advocating that "... within the near future all research on mice should be carried out on inbred animals or on hybrid mice of known (genetically controlled) origin, where the degree of biological variability has been carefully controlled". As immunological studies developed, this became essential; but as a consequence laboratory mice became more and more removed from their origins.

There are now about 200 highly inbred strains of mice. However the great bulk of these arose from a very narrow base — notably the mouse colony established in Granby, Massachusetts during 1903-15 by Miss Abbey Lathrop, who supplied, among others, W.E. Castle and C.C. Little. The origins of her mice are not known in detail but they included 'fancy' mice imported from various European countries and wild animals from Vermont and Michigan, which were crossed to them. Such widely used strains as the C57 group are descended from the Lathrop colony.

The genetical poverty of established laboratory strains as a result of their small number of ancestors has led in recent years to an interest in wild mice as a source of new inherited variants: the first mouse inborn error of metabolism analogous to a human anomaly (histidinaemia) was discovered in a mouse from Peru; several mice caught five years ago in Taunton were found to have a similar defect in pyruvate kinase to one which produces a clinical anaemia in man. More recently mice from south east Asia (notably *M.m. castaneus* and *M.m. molossinus*) have proved particularly rich in previously unknown variants.

An older line of research in wild mice stems from the widespread occurrence of *t*-alleles in natural populations. Work on the *t*-complex has been stimulated in the past few years because of its linkage to the major histocompatibility complex (*H-2*), with suppression of crossing-over between the two chromosomal segments if a *t*-allele is present. It has been suggested that the *t* and *H-2* segments may represent a duplication, *t* acting as a tissue recogniser before birth and *H-2* taking over post-natally.

Finally, mice have been important to evolutionists because of their apparently very tight social structure, from which it has been argued that the 'effective population size' of mouse populations is less than four individuals, thus permitting considerable genetic drift between generations and providing a paradigm for testing ideas of neutrality and selection acting on particular inherited variants.

All these interests found a focus in a symposium on the house mouse held in London recently*. It reviewed developments over a wide range of fields from archaeology and taxonomy to gerontology and zoonoses. As such it established hybrid vigour between different disciplines rather than transitory euphoria from exciting experiments. The recurring theme was the problem of identifying the stresses and stratagems of animals exposed in different parts of their range to widely differing environmental conditions. R.J. Berry (Royal Free Hospital Medical School, London) described gene frequency changes of over 15% between cohorts of mice in the same populations living on sub-Antarctic islands, with the two sexes showing changes in opposite directions on South Georgia. No changes occurred in populations living on tropical Pacific islands. But what do these changes mean? J. Klein (University of Tübingen) suggested that the levels of heterozygosity (over 95%) found at the major histocompatibility locus *H-2* (Duncan *et al. Nature* **281,** 603; 1979) are the result of selection by pathogens acting on varying gene pools established by small numbers of founders. This interpretation depends to some extent on a deme structure of mouse populations allowing local differentiation, and the hitherto generally accepted tightness of this structure was challenged from the point of view of ethological and chemical interactions between individuals by J.H. Mackintosh (Birmingham) and Jane Smith (Pest Infestation Control Laboratory, MAFF).

Implicit in all these approaches was the recognition that both an individual mouse and a mouse population changes in time. This was spelt out by D. Bellamy (Cardiff) who emphasised that many influences are involved in ageing, and it is dangerous to assume that a wild mouse which reaches its physical peak at around 100 days and dies at 400-500 days (even in the laboratory) is responding to the same processes as an inbred animal which may live up to 800 days. A similar point was made by M.E. Jakobsen (North East London Polytechnic) in criticising the naivety inherent in many laboratories studies of physiological responses (particularly brown fat amount and turnover) when compared with the complex and variable interactions of behaviour and time in mice living in nature.

Notwithstanding, one of the values of the house mouse is the possibility of feedback between knowledge gained of animals living under wild conditions and those kept under controlled conditions in the laboratory. Mary Lyon (MRC Radiobiology Unit, Harwell) reviewed the complexity of gene action in the supergenes on chromosome 17, where embryological analysis of the effects of different loci is a necessary complement to Klein's immunological work. The potential of laboratory animals for interpreting the wild situation (and *vice versa*) was also apparent in contributions from R.C. Roberts (ARC Unit of Animal Genetics, Edinburgh) on the determinants of growth (strong selection for small size in laboratory mice failed to reduce them to the mean size — around 9 gram — of animals from the tropical Pacific) and Jo Peters (MRC Harwell) on protein variation, while J.G.M. Shire (Glasgow) showed how laboratory studies on wild caught mice had influenced — and could enrich — our understanding of endocrine action by providing new structural variants of hormones and by affecting target organ sensitivity.

Surprisingly, the most radical papers came from two taxonomists, J. Marshall (US Natural History Museum) and L. Thaler (Montpellier) who broke the news that the unitary widespread Linnaean species *Mus musculus* with four recognised and 164 invalid subspecies is no more. Thaler spoke merely of species nos 1, 2, 3 and 4 in Europe, but Marshall went the whole taxonomic hog and gave us *Mus musculus, domesticus, spretus* and *abbotti* (=*spicilegus*) in western Europe, *hortulanus* in eastern Europe, *molossinus* in Japan, and *castaneus* as an Asian commensal.

But house mice are even more complicated: traditionally they have had 20 pairs of very uniform acrocentric chromosomes, but local races with 11, 13 and 14 pairs of chromosomes due to centric fusion are now known, and these naturally occurring chromosomal anomalies can be used to produce aneuploid mice, and hence study the pathological effects of aneuploidy (A. Gropp, Lubeck). A new Robertsonian fusion (with 38 chromosomes) from an Orkney island was reported by Klein. No-one knows why these chromosomal races have arisen, and why they persist.

The implications of our knowledge of house mice for ecologists are great: we know more about the behaviour and

genetics of this species(s) than any other. But the real significance of house mouse biology is for biomedical workers: their inbred strains ought no longer to be regarded merely as biochemical artefacts, but as interacting feedback systems dependent on an evolutionary history of adaptation and opportunism. It is pertinent that 13 of the 22 speakers at the Zoo Symposium were employed in Medical Schools or by the MRC.

As medical resources become increasingly stretched, they will have to be applied more consciously at points of need rather than in blunderbuss endeavours to improve the 'environment' (such as water quality, toxicological and dietary hazards, or prenatal care). Wild house mice provide a logical step in interpreting results obtained in the artificiality of the laboratory environment to the confusing heterogeneity of human life. It is to be hoped that the symposium will stimulate both research and funding for work on naturally-living mice. ☐

Why ppGpp?

from Andrew Travers

THE ubiquity of purine nucleotides as regulators of macromolecular synthesis was highlighted last summer at a workshop most appropriately dedicated to Fritz Lipmann*. Historically the identification of regulators such as cyclic AMP, ppGpp, pppAppp, A$^{5'}$ pppp$^{5'}$ A and 2′5′ oligo-A has depended on their unusual and often bizarre structutes. Yet in evolution such control systems are unlikely to have arisen *de novo*. Rather it seems more probable that they initially evolved as more effective analogues of pre-existing systems. Such analogues should necessarily be chemically similar to the primordial regulators yet should possess some distinguishing structural features which would allow greater precision in the control of their intracellular concentration.

ppGpp may be considered as a paradigm of such an effector. Its accumulation in bacteria is elicited both by energy starvation and amino acid starvation and, in general, is accompanied by the reduction of protein and RNA synthesis to basal levels. Both genetic (A. Atherley, Iowa State University, Ames; M. Cashel, National Institutes of Health, Bethesda) and biochemical analysis (D. Richter, Universität Hamburg; J. Sy, Rockefeller University) indicate that there are two pathways for its synthesis, one dependent on ribosomes and activated by uncharged tRNA and a second whose activity is apparently independent of protein synthesis. Similarly the degradation of ppGpp to either ppGp or ppG may be equally complex (Richter).

What is the role of ppGpp? The isolation of a viable mutant which lacks detectable ppGpp clearly demonstrates that the nucleotide is dispensable during normal growth (Cashel). However the ability of the mutant to undergo growth transitions is somewhat impaired. One correlation with the accumulation of ppGpp consequent on environmental stress is a change in transcriptional selectivity manifested as a preferential shut-off of stable RNA production. *In vitro* physiological concentrations of the nucleotide inhibit the initiation of rRNA synthesis with either promoter bound or free RNA polymerase as its target (M. Gruber, Rijiksuniversiteit, Groningen; A. Travers, MRC Laboratory of Molecular Biology Cambridge). Yet the extent of inhibition of rRNA synthesis *in vitro* is insufficient to account for the *in vivo* effect. Either the *in vitro* system lacks an activator normally present *in vivo* or ppGpp is not the immediate effector of transcriptional changes following amino acid starvation. Indeed a minor guanine nucleotide, ppGp, was proposed as a candidate true regulator (J. Gallant, University of Washington, Seattle).

Although most evidence favours the hypothesis that ppGpp is a major regulator of macromolecular synthesis during nitrogen starvation analogous changes in gene expression can occur without the concomitant accumulation of this nucleotide. This phenomenon is seen in strains containing mutations in the gene encoding fructose 1:6 diphosphate aldolase (Atherley; Bock & Neidhardt *J. Bact.*, **92**, 470; 1966). This observation again points to the possibility that the response of transcription to environmental stress depends on the balance between the levels of a number of effectors. Such a mechanism would allow diverse means of eliciting the same response. One example of this phenomenon is the process of sporulation in *Bacillus subtilis*. This can be induced by either nitrogen or energy starvation. The latter results in a substantial increase in the intracellular concentration of an adenine nucleotide tentatively identified as pppAppp (H. Rhaese, Universität Frankfurt). By contrast, on nitrogen starvation the GTP pool falls without a concomitant increase in pppAppp levels (E. Freese, National Institutes of Health, Bethesda). In both cases the correlation between the observed phenomena and the physiological response is strong and suggests a causal effect. To reconcile such apparently disparate observations it has to be argued that a fall in the GTP pool is equivalent to a rise in the pppAppp pool. This would be compatible with the opposing functional effects of adenine and guanine nucleotides on RNA polymerase.

Although the appearance and immediate effects of regulatory nucleotides such as ppGpp and pppAppp may be transient there is much evidence to suggest that their long term effects may also be important. The accumulation of ppGpp is accompanied by the preferential synthesis of two proteins, B56.5 and stringent starvation protein (Reeh *et al. Molec. gen. Genet.* **149**, 279; 1976). At least the latter binds to RNA polymerase and seems to alter its properties in a similar manner to ppGpp itself (Ishihama & Saitoh *J. molec. Biol.* **129**, 517; 1979). Thus ppGpp may induce the synthesis of proteins which act to stabilise the effect which the nucleotide itself elicits. Such a process would constitute a mechanism for changing the state of the cell. In a like manner the 37,000 molecular weight polymerase binding protein which appears in the initial stage of sporulation in *B. subtilis* (Haldewang & Losick *Nature*, **282**, 256; 1979) could stabilise the effects of the transient perturbation of the adenine and guanine nucleotide pools.

In eukaryotes, with the exception of cyclic AMP, there is little evidence for selective regulators of gene expression analogous to ppGpp. In yeast changes in nucleotide pools similar to those observed in *B. subtilis* are correlated with sporulation (Freese; Rhaese). Yet in higher eukaryotes ppGpp and similar compounds are apparently absent (R. Silverman, Iowa State University). Nevertheless highly phosphorylated compounds were reported to accumulate after heat shock in *Drosophila* (Travers) and immediately before sporulation in the water mould *Achyla* (H. Lejohn, University of Manitoba, Winnipeg). Although the appearance of these compounds correlates with changes in macromolecular synthesis there is as yet no conclusive evidence as to whether they have a regulatory role. However adenine nucleotides have been implicated as signals for the initiation of DNA replication. One proposed universal regulator is A$^{5'}$ pppp$^{5'}$ (P. Plesner, Odense University), which binds tightly to a single subunit of DNA polymerase α (F. Grummt, Max-Planck Institut für Biochemie, München). Alternatively, the effective signal could be the balance between ATP and ADP in the cell nucleus (E. Rapaport, Harvard University). Such a mechanism would utilise purine nucleotides required for essential intracellular processes, a characteristic which might also be expected to typify early stages in the evolution of regulatory processes.

If adenine nucleotides act as indicators of the energy balance within the cell what is the evolutionary origin of the guanine nucleotide regulators? In bacteria the major physiological role of guanine nucleotides is their involvement in protein synthesis which generates GDP from GTP. ppGpp and related nucleotides could thus be derived from a primitive regulatory system utilising the simple 5′ di and triphosphates for coupling transcription and translation. ☐

Scenario for a warm, high-CO_2 world

T. M. L. Wigley, P. D. Jones & P. M. Kelly

Climatic Research Unit, University of East Anglia, Norwich, UK

Plausible patterns for temperature and precipitation changes accompanying a general global warming, such as might occur due to a large increase in atmospheric carbon dioxide levels, are presented. The patterns are determined by comparing the five warmest years in the period 1925–74 with the five coldest in this period. Temperature increases are indicated for most regions, with maximum warming over northern Asia. A few isolated regions show cooling. Precipitation changes are fairly evenly distributed between increases and decreases; the most important features being an increase over India, and decreases in central and south-central USA and over much of Europe and Russia. The latter decreases, should they occur, could have considerable agricultural impact.

MAN has upset the global carbon cycle by burning fossil fuels and, probably, by deforestation and changing land use. The net result of these activities is to increase the CO_2 content of both the atmosphere and the oceans. Although some details of the carbon cycle remain to be determined[1], it is generally believed that if fossil fuel use continues to increase at about the rate of increase experienced over the past century then atmospheric CO_2 levels will reach roughly twice today's level by the middle of the next century[2,3]. Furthermore, the enhanced greenhouse effect, could well cause a significant increase in global mean annual surface temperature. Numerical modelling experiments suggest that this increase would be 2° to 3 °C (refs 4–6), a change as great as or greater than any which has occurred in the past 10,000 years. The magnitude of the increase is, however, uncertain and a CO_2-induced warming could possibly be offset by a natural cooling trend and/or by the effects of various feedback mechanisms (such as that due to possible changes in cloud cover).

Although there is some reason to doubt that a significant warming will occur, its consequences are so great that the possibility must be considered seriously. We will, for the purposes of this article, assume that a global warming will occur. If it does then relatively large shifts in the main atmospheric circulation systems would accompany such a change. These circulation changes will determine the geographical patterns of the changes in temperature, precipitation and winds. Although most regions are expected to warm, the amount of warming must vary considerably from place to place[7], and it is possible that some regions will become cooler; and although global average precipitation is expected to increase[8–10] some parts of the world will most probably become drier[8,9]. To assess the impact of these changes on society and decide on possible ameliorating courses of action, one must evaluate impacts on a regional scale. It is therefore essential to have some idea of the spatial distribution of future changes in climate. We present here a meteorologically and climatologically self-consistent (that is 'realistic') scenario for the pattern of changes based on recent instrumental records of the natural year-to-year fluctuations in climate.

Insights into a warm world

Two approaches may be used to derive a scenario for the pattern of climatic changes which might result from a large increase in atmospheric CO_2. These are: numerical modelling using general circulation models (GCMs)[10–12]; and the use of past warm periods as analogues of the future[8,9]. The latter includes the possibility of using recent instrumental data to determine the characteristics of individual warm years which may then be used as analogues of the future.

Both methods have their limitations. GCMs are restricted by their present state of development; current computer power dictates that these models simulate in detail only one part of the atmosphere–hydrosphere–cryosphere system. Most models only consider the atmosphere and use the hydrosphere and cryosphere as externally specified boundary conditions[11]. GCMs do, however, simulate present-day climate reasonably well; and, provided sea-surface temperatures and ice margins are prescribed, they also appear to simulate ice-age climate in a realistic way[11,13]. For a high-CO_2 world we cannot accurately prescribe sea-surface temperatures and should ideally use a coupled ocean-atmosphere model. Although such models do exist, their simulation of the thermodynamics and dynamics of the oceans is still at a rudimentary level.

Although there is agreement on many of the general results for the high-CO_2 world which have been estimated using GCMs (and other, simpler models), the only spatial detail which has been estimated is the latitudinal variation of changes in temperature[4,6,10]. These results indicate that the greatest temperature changes will occur at high northern latitudes (particularly above 60°N) and in winter. In these respects, expected CO_2-induced temperature changes show a similar dependence on latitude and season as do the 'natural' fluctuations which have occurred this century: maximum natural variability occurs in winter and in the latitude band 50 to 70°N[14,15].

The second method is to use the past as an analogue for the future. Four possible candidates have been described by Flohn[16–18]: the mediaeval warm period (about AD 800–1200), the Holocene warm period known as the Hypsithermal or Altithermal (around 4,000 to 8,000 yr BP), the last (Eemian) interglacial (isotope stage 5e, about 120,000 yr BP), and the last period when the Arctic Ocean was believed to be ice free (before 2.5×10^6 yr BP). These times are possible analogues for progressively warmer future climates. As Flohn points out, the extent to which these times may be useful as analogues depends in part on how well the ocean and cryosphere boundary conditions which occurred in the past compare to those which might occur in the future. In all four cases, boundary conditions were increasingly different from today. A further difficulty in using any of these periods as analogues is that the available data are quite sparse and are generally indirect and qualitative.

The most detailed analysis of a past epoch as an analogue for a future warmer world is Kellogg's[8,9] analysis of the Hypsithermal. (Sarnthein[19] has also made a detailed study of this period, although not as a warm world analogue.) Kellogg has used published interpretations of pollen data to compile a picture of summer precipitation patterns relative to the present.

)028–0836/80/010017—05$01.00

Unfortunately, these data are often poorly dated, and what appears to be a synchronous spatial pattern may be the superposition of a number of episodes which all occurred at slightly different times. Nevertheless, Kellogg's picture of global precipitation during the Hypsithermal is widely quoted as an analogue for a high-CO_2 world.

The recent past, for which instrumental records are available, may also be used as a guide to establishing possible future patterns of climatic change. The mean annual surface temperature of the Northern Hemisphere (and quite probably of the whole globe) varies considerably from year to year. Because of this variability one can select individual warm years as analogues for a future warmer world (resulting from increased CO_2, or other causes); or, alternatively, use a composite of a number of warm years as a warm world analogue. We have used this method in the present study. A similar approach has been used by Williams[20], Namias (unpublished) and Drozdov[21] (although this latter work was not directed towards the CO_2 issue.)

The use of any past records as analogues for a future high-CO_2 world can be criticised on the grounds that past climatic fluctuations were not caused by changes in atmospheric CO_2 content. Although the causes of year-to-year fluctuations in this century are not clearly understood, CO_2 is not a possibility. In defence against this criticism we note that numerical model results indicate that, whatever the cause of the warming, there are broad similarities in the patterns of climatic change. The computed effects of, for example, an increase in the solar constant[12] are similar to those due to increased atmospheric CO_2[4]. Furthermore, as noted above, what little is known about the latitudinal and seasonal variations in temperature changes which might result from increased CO_2 indicates that these variations are similar to those for natural year-to-year temperature changes. Essentially, in making use of natural fluctuations we are assuming that, given similar boundary conditions, there are broad similarities in the way the atmosphere responds to different types of forcing.

Scenario for a high-CO_2 world

Instead of comparing a group of recent warm years with the long-term mean in order to derive a warm-world scenario, we have used the variations in mean annual surface temperature to maximum advantage by comparing a composite of the five warmest years in the period 1925–74 with a composite of the five coldest years in this period. The period 1925–74 has been chosen because, although temperature data exist before 1925, there are substantial gaps in the coverage and problems of comparability of early and more recent records which make it difficult to rely on the values of, and changes in, spatial means and patterns.

We have chosen to define 'warmest' and 'coldest' in terms of the latitudinal zone 65° N to 80° N. This choice is based partly on data availability, but also on the generally accepted belief that CO_2-induced changes will be greatest in high northern latitudes. The use of high-latitude data eliminates many of the large data-poor ocean areas. To facilitate averaging over arbitrary regions of the globe, and to produce a homogeneous data series over the whole period, we calculated mean temperatures by first calculating grid point temperatures from station data. Our methods differ slightly from other authors, but our results correlate highly with those of Budyko[22], Reitan[23], Angell and Korshover[24] and Borzenkova *et al.*[25].

For the 65° N to 80° N zone the five warmest years are 1937, 1938, 1943, 1944 and 1953, and the five coldest years are 1964, 1965, 1966, 1968 and 1972. The average temperature difference between the warm and cold year groups is 1.6 °C for the high latitude zone, and 0.6 °C for the Northern Hemisphere as a whole, and the years themselves reflect the general warmth of the 1930s and 1940s and the subsequent cooling of the Northern Hemisphere. When the winters are compared (for the high latitude zone), the warm-year group is, on average, 1.8 °C

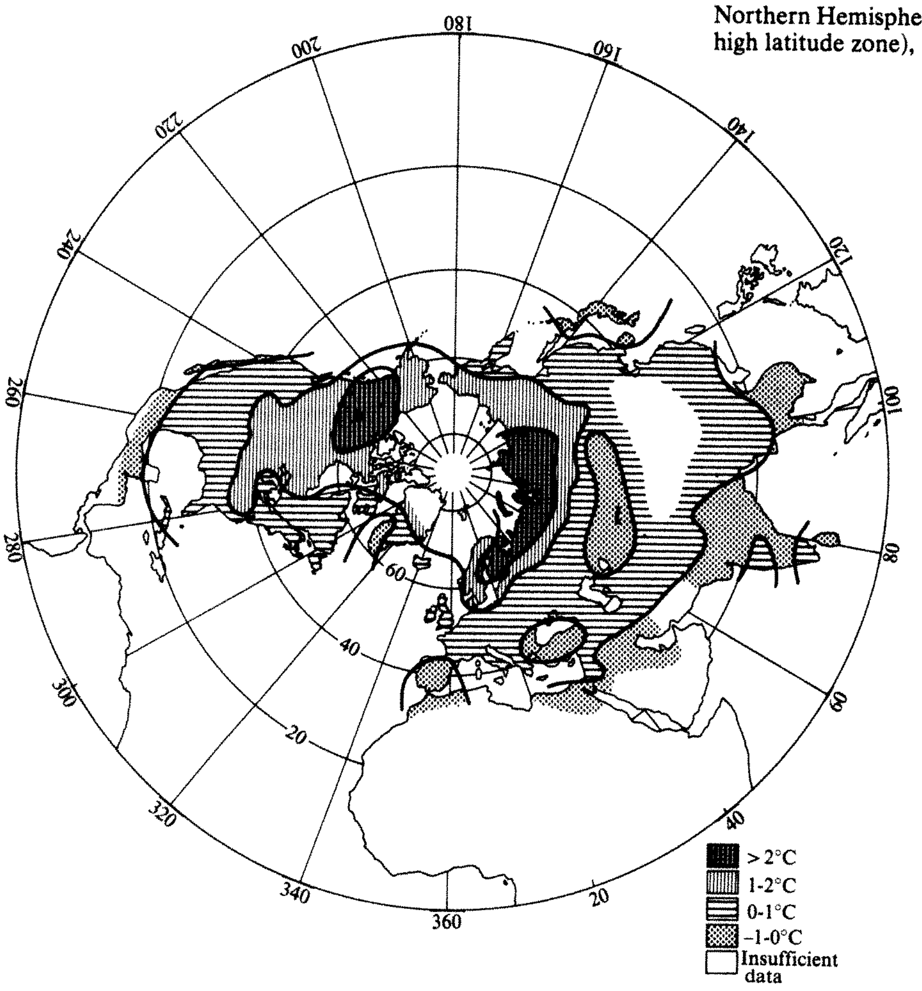

Fig. 1 Mean annual surface temperature changes from cold to warm years. The corresponding change in the hemispheric mean temperature is 0.6 °C. For reference, the expected change in global mean temperature due to a doubling of atmospheric CO_2 concentration is ~2 °C.

warmer than the cold-year group; for the summers the corresponding difference is 0.7 °C. This greater sensitivity in winter is in accord with expectations for the high-CO_2 world based on numerical modelling results[10]. All of these differences are statistically significant at the 5% level; the annual differences being significant at better than the 0.1% level. This is an important point since it justifies the use of the two groups as analogues of separate populations, even though they have been derived from a single population.

We now find the spatial patterns of temperature and precipitation differences between the cold- and warm-year groups. These patterns (Figs 1 and 2) provide a scenario for (but not a prediction of) the changes in climate which might accompany a CO_2-induced global warming. Since modelling results suggest that a doubling of CO_2 will warm the globe by 2 °C or more, the magnitude of CO_2-induced temperature changes may be somewhat larger than the differences shown in Fig. 1.

Figure 1 shows the spatial pattern of mean annual surface temperature differences between the cold- and warm-year groups. This map has been constructed from station rather than grid-point data, based on data from 219 stations. Maximum warming occurs in high latitudes and in continental interiors; up to more than five times the hemispheric mean increase in a region extending from Finland across the northernmost parts of Russia and Siberia to about 90° E. Not surprisingly, this area coincides with the region of greatest natural temperature variability. A large part of North America has positive temperature changes of two or more times the hemispheric mean, and this region extends westwards from Alaska, across northern Asia and into Scandinavia. In contrast, some regions show negative differences; Japan, much of India, an area including and adjacent to Turkey, the Iberian peninsula and adjacent North Africa, the south-west coast of the US, a region in central Asia and southwestern Greenland.

An examination of the surface pressure pattern differences between cold and warm years shows that the warm years have intensified high-latitude (50° N to 70° N) westerlies, greater cyclonic activity in the arctic and subarctic regions of the eastern hemisphere, and a westward displacement of the Siberian High in the winter half of the year. These features are consistent with the observed temperature differences. The shift in the Siberian High helps to explain the cooling zone in central Asia, which is largely an autumn and winter phenomenon.

Figure 1 only shows differences in mean annual temperature. Seasonal temperature changes are equally important and require further analysis. Most of the large differences which occur at high latitudes, although in the same sense for all seasons, are greatest in winter. In North America there is, in general, warming in all seasons: in the central region north of 40° N the warming is greatest in autumn, while for the rest of the continent (including Alaska) it is greatest in winter. The cooling zone around Turkey is due mainly to cooler springs: summers are generally slightly warmer. In India the cooling is greatest in summer and autumn; in winter and spring there are minor differences of both signs and a considerable degree of spatial variability. Finally, the cooling of the south-west coast of the US is a maximum in summer and the winters are actually warmer.

Figure 2 shows the distribution of precipitation changes from cold to warm years, based on data from 215 stations (most, but not all, being those used in Fig. 1). Precipitation patterns generally have greater small-scale spatial variability than temperature patterns, so the picture presented here is only a guide to broad-scale patterns. When averaged over the Northern Hemisphere we found that the warm-year groups showed a slight (statistically insignificant) increase in annual precipitation of between 1 and 2% compared with the cold-year group. Numerical modelling results indicate that an overall increase of around 5% might accompany a doubling of atmospheric CO_2[10].

The most important features of Fig. 2 are decreases in precipitation over much of the US, most of Europe and Russia (especially France, Spain and the Central Russian Plain) and over Japan, and increases in precipitation over India and the Middle East. For India, the increases vary from a few per cent in Bangladesh and along the eastern coast, to almost 100% in the north-west. Decreases in precipitation occur in southern India and in the north around New Delhi. In spite of these considerable variations, a clear spatial pattern is apparent, indicative of a more intense monsoon circulation in the warm years. Some of the features in Fig. 2 are the same as those which occurred during the Hypsithermal, the period used by Kellogg[8,9] as an analogue for a future high-CO_2 world. However, there are notable differences. Kellogg shows a wetter Europe and Russia and drier conditions over northwestern Canada, in contrast to our results. Some of these differences probably arise because Kellogg's reconstruction reflects summer precipitation, but the different boundary conditions which prevailed during the Hypsithermal must also be a significant factor.

The seasonal distribution of precipitation changes is important in determining impact. In particular, the consequences of a drier (and warmer) Europe and Russia deserve further consideration. The reductions in rainfall shown in Fig. 2 are not evenly distributed over the year. Largest reductions occur mainly in winter and autumn; but most regions (especially eastern Europe) also show reductions in summer precipitation. A few stations (Lyons, Madrid, Lisbon, Vienna) have greater summer rainfall in the warm years. In the UK annual precipitation changes are minor, except for southern England where precipitation is less in the warm years (spread fairly evenly over winter, spring and summer). For other parts of the UK, although annual changes are small, most places show reductions in spring rainfall and increases in summer rainfall. For the central and western parts of the USA, where there is a reduction in annual precipitation, increases in the winter and spring and decreases in the summer and autumn dominate the picture. Further north, in Canada, summer precipitation increases.

Changes in boundary conditions

The present results are based on climatic fluctuations which occur on the year-to-year time scale. Climate changes on many time scales (in fact, the effects of increased CO_2 are relatively slow), and there are important changes which have occurred on time scales too long to be noticeable in the record of the past 50 years. In general, these slow changes have been associated with larger changes in ocean and cryosphere boundary conditions than have been observed this century. Similarly, a large warming at high latitudes will probably lead to changes in Arctic sea ice extent, ocean current systems and sea surface temperatures which are outside the range of variations experienced during the past 50 years. These changes in the boundary conditions for the atmosphere require further discussion since they are central to the use of the past as an analogue and to the use of GCMs in modelling conditions in a warmer world.

It has been suggested that CO_2-induced warming may cause seasonal melting of the Arctic sea ice[8,16,27]. How much warming is required for this is uncertain. Manabe's simulation with four times the pre-industrial CO_2 level [10] showed the sea ice disappearing in summer, and this is commensurate with the work of Budyko[26] and Parkinson and Kellogg[27] which suggests that a summer temperature increase of 4–5 °C in the Arctic Basin would be required to melt the sea ice in summer. These results indicate that sea ice boundary conditions will probably not alter significantly beyond the extremes of the past 50 years at least until the early decades of the twenty-first century: although proposed alterations to the flows of major northward-flowing Russian rivers[28,29] might accelerate Arctic sea ice changes.

We have examined sea ice extent in our cold and warm year groups and found there to be notable differences. Two of the warm years (1937 and 1938) were remarkable for a major reduction in the summer ice along the north coast of Asia and increased outflow of ice from the Arctic in the East Greenland current. Further details are given by Koch[30].

Sea-surface temperature (SST) patterns form the other main atmospheric boundary condition. In GCM simulations, SSTs are

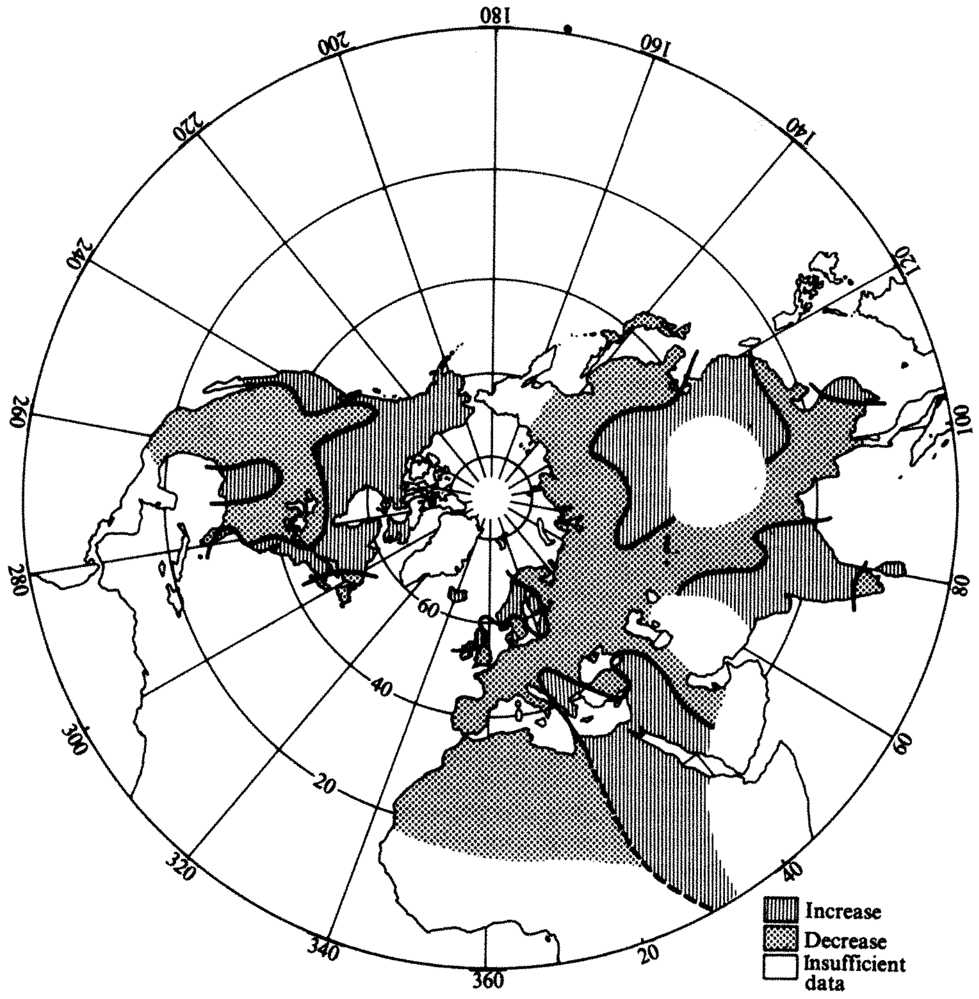

Fig. 2 Mean annual precipitation changes from cold to warm years.

either prescribed (in atmosphere-only models) or determined interactively (in coupled ocean–atmosphere models). Because of data deficiencies we have not been able to examine SST differences between our cold and warm year groups in any detail. We find however, a strong indication that SSTs over most of the North Pacific were cooler in the warm years. Ocean currents are also important, partly because of their relationship with SST patterns, but also because they are responsible for large amounts of latitudinal heat transport. No GCM with realistic ocean currents has been applied to the CO_2 problem. There are insufficient data available to study the details of changes this century, but we note that quite large changes in the Gulf Stream are thought to have occurred in earlier centuries[31].

Ocean current changes are linked to changes in atmospheric circulation patterns; in particular to changes in surface wind stress. Any significant wind stress reduction would be important because it would result, not only in a change in ocean current dynamics, but also in reduced mixing in the upper layers of the ocean and reduced upwelling, both of which would have profound effects on marine life through changing nutrient supply rates. Budyko and Vinnikov[32] have argued that the mean surface wind stress in a high-CO_2 world might be as little as 50% of today's value. In examining the mean surface wind stress (based on the geostrophic wind) in our warm and cold year groups we found the differences to be small, amounting to only a few per cent and contrasting with the prediction of Budyko and Vinnikov[32]. Although this result is reassuring, further examination of possible regional changes in wind stress is required.

Conclusions

We have used the word 'scenario' deliberately to distinguish our results from a 'prediction'. A scenario can only provide a guide to the patterns of climatic change which could occur accompanying a global warming. Our results are limited to relatively small changes in ocean and cryosphere boundary conditions, changes which might well be exceeded in the early decades of next century. Further, as the average hemispheric mean temperature differences between the warm and cold year groups is 0.6 °C, and because changes in regional climate may be non-linear with respect to global or hemispheric temperature change (especially when large changes in boundary conditions are involved), our scenario is most probably only representative until around the turn of the century. It would be dangerous to put any faith in extrapolations which involve hemispheric mean temperature shifts of more than 0.6 °C from the present.

Because the scenario presented here is based on mean conditions for two five-year groups, it is only representative of 5-year to decadal mean conditions. Superimposed on such conditions one must expect a 'normal' amount of year-to-year variability. Whether this variability will be less or more than the present is a controversial issue. Although a link between mean surface temperatures and mean variability may exist, the link is neither simple nor obvious, as van Loon and Williams[33] have shown. We can be sure that the climate will continue to vary considerably from year to year (just as the individual years in our warm and cold groups show noticeable differences), so even in a warm high-CO_2 world there will be regional extremes of warmth and cold, wetness and dryness which will differ markedly from 5 to 10-year mean patterns.

What would be the human (social, economic and political) impact of changes of the type presented here? We can only speculate on some of the possibilities—while noting that impact is at least as much related to the year-to-year variability of climate as it is to the mean or to changes in the mean. First, a substantial increase in the intensity of the Indian monsoon could have a significant impact. Although the impact of the monsoon in India is generally linked to its failure, increased and more violent precipitation can also have most detrimental effects (as witnessed by the flooding in 1979). Second, in some parts of the world (in particular in Europe and European Russia) temperature increases may occur in association with reductions in precipitation. These two factors will reinforce each other in increasing soil moisture deficits and so tend to have greater agricultural impact than either factor would alone. The climatic differences between warm and cold years which we have shown for Europe and European Russia appear to be of special importance as they indicate that conditions in a high-CO_2 world could be radically different from those given by Kellogg for the Hypsithermal.

We stress that the results presented here are little more than a guide to the type of climatic conditions that are possible in a high-CO_2 world. Should a global warming occur it will, however, certainly affect the weather patterns and climate regimes of the world and the effects will be different in different regions. These changes will, at the very least, result in shifts of agricultural zones, and some regions will be affected adversely, some favourably. Although some of the effects of a global warming (caused by CO_2 increases, or for any other reason) may well be beneficial[34], our scenario does show that detrimental effects could occur in some parts of the world, and our work highlights the need for more research into the interdisciplinary problems associated with climatic change which are focused by the current interest in the CO_2 issue.

This work was supported in part by grants from the US Office of Naval Research, the US Department of Energy and a consortium of insurance companies (Eagle Star, General Accident, Guardian Royal Exchange, Legal and General, Phoenix, Prudential, Sun Alliance and London). Oxygen and strontium isotope relationships in the British late Caledonian granites

Russell S. Harmon & Alex N. Halliday

Isotope Geology Unit, Scottish Universities Research and Reactor Centre, East Kilbride, UK

~~R508~~ R409

Oxygen and strontium isotope data for 25 late Caledonian granite plutons emplaced between ~435 and 390 Myr indicate that the parent magmas were hybrids, derived from partial fusion of mantle-like material and varying proportions of a crustal component.

COMBINED stable and radiogenic isotopic studies can provide important information concerning both the origin of granite magmas and the post-emplacement history of volcanic and plutonic igneous rocks[1,2]. In this article we present the results of a combined O–Sr reconnaissance isotopic study of twenty-five ~400-Myr-old Caledonian granitic plutons from Scotland and northern England and assess the extent to which crustal anatexis and/or assimilation was important in the generation and subsequent evolution of the parent magmas.

The Caledonian fold belt is thought to have formed as a result of the closure of the 'Iapetus' ocean basin during Lower Palaeozoic times[3]. Granitic magmas were intruded into Precambrian and Lower Palaeozoic country rocks between approximately 640 and 390 Myr (refs 4, 5). Most important spatially and volumetrically are the late Caledonian granites, the 'Newer' and 'Last' granites of Read[6]. These post-tectonic, largely undeformed granites include those emplaced by active injection into country rock with concordant migmatisation and veining (forceful 'Newer' granites) and those emplaced in ring complexes associated with tensional faulting and cauldron subsidence (passive 'Last' granites). Read[6] separates these two classes in time, arguing that deposition of the Lower Old Red Sandstone occurred between emplacement of the forceful 'Newer' and passive 'Last' granites. Apart from those of the north-east Grampian region[4] only a few reliable radiometric ages for the forceful 'Newer Granites' have been published (for example, Strontian, 435 ± 10 Myr)[7] and the oldest reasonably reliable published age for a passive cauldron subsidence granite is that for Lochnagar (415 ± 5 Myr)[5]. However, the temporal classification of Read[6] cannot be applied throughout the British Isles. In Donegal, for example, forceful emplacement (the Main Donegal granite) post-dates passive emplacement (Rosses

Table 1 Rb–Sr analyses (new) for four Grampian Highland granitoids

Pluton*	Rb (p.p.m.)	Sr (p.p.m.)	Rb/Sr (weight)	^{87}Rb/^{86}Sr (atomic)	^{87}Sr/^{86}Sr (atomic)	(^{87}Sr/^{86}Sr)$_t$†
Ballachulish-I	65.72	1568	0.04193	0.1213	0.70495	0.70424±4
Ballachulish-II	85.88	1203	0.07141	0.2066	0.70553	0.70433±6
Ben Nevis	101.1	734.2	0.1377	0.3982	0.70662	0.70430±5
Moor of Rannoch	62.03	1581	0.03923	0.1135	0.70548	0.70482±7
Garabal Hill	94.40	638.2	0.1479	0.4280	0.70988	0.70741±7

All analyses utilised isotope dilution and an MM30B mass spectrometer. Uncertainties (2σ) are ±0.7% for ^{87}Rb/^{86}Sr and $<\pm 0.01\%$ for ^{87}Sr/^{86}Sr. NBS 987 gave a value of 0.71020±3 (2σ for two analyses) at the time of these measurements.

* Sample locations and ages are given in Table 2.

† Combines estimated uncertainties for (^{87}Sr/^{86}Sr) with (^{87}Rb/^{86}Sr)($e^{\lambda t}-1$) quadratically; uncertainty in t (the estimated age) not included; $\lambda^{87}\text{Rb} = 1.42\times10^{-11}$ yr^{-1}.

Complex) with all granites emplaced close to 410 Myr (ref. 8 and A. N. H., M. Aftalion and B. E. Leake, unpublished). Similarly, the Fleet pluton of the Southern Uplands in Scotland was emplaced forcefully at 392±2 Myr (ref. 9).

In general, the late Caledonian granites have the calc-alkaline characteristics typical of plutonic rocks emplaced at destructive plate margins[9–11]. The 25 plutons sampled in this study comprise a majority of the late Caledonian granites but do not include the ~460-Myr-old granites studied by Pankhurst[4]. Many of the plutons are composite and zoned. The samples analysed, broadly described as 'granitic', range in composition from diorite and tonalite, through granodiorite, to peraluminous granite with chemical variation continuous among the various rock types. Petrographically and chemically the granitoids span the range from 'sedimentary' to 'igneous' type as defined by Chappell and White[12] with no discernible geographical pattern to their distribution. Recent zircon U–Pb, Rb–Sr, and common Pb reconnaissance studies[5,7,13] have revealed a general pattern of inherited zircon U–Pb memory north of the Highland Boundary Fault, generally low initial Sr isotope ratios (<0.709), and a tendency for Pb to be increasingly radiogenic southwards across the region.

Isotopic ratio determinations

Oxygen was extracted from whole rock powders by reaction with BrF_5 and converted to CO_2 as described by Clayton and Mayeda[14]. ^{18}O/^{16}O ratios, determined on the CO_2 gas using an AWRE Aldermaston isotope ratio mass spectrometer, are reported here in the 'δ' notation relative to standard mean ocean water (SMOW) as defined by the Snowbird Quartz (+16.20‰) and African Glass Sand (+9.60‰) standards. Overall precision is 0.1–0.2‰. The Sr isotope ratios presented here are chiefly those reported by Halliday *et al.*[5,9] but include new data (Table 1) for four southwestern Grampian Highlands granites (Ben Nevis, Ballachulish, Moor of Rannoch, Garabal Hill). (^{87}Sr/^{86}Sr)$_i$ ratios were calculated from (^{87}Sr/^{86}Sr) ratio measurements corrected for ^{87}Rb decay using independent K–Ar, Rb–Sr and U–Pb ages or from Rb/Sr isochron regression. Samples for which the ages are not accurately known (such as Cluanies) have such low Rb/Sr ratios that the calculated (^{87}Sr/^{86}Sr)$_t$ ratios are very close to initial ratios.

The O and Sr isotopic data for this reconnaissance study of the ~400 Myr Caledonian granitoids are presented in Table 2 and, averaged for each pluton, are plotted geographically in Fig. 1. No regional distribution pattern is apparent for either δ^{18}O values or (^{87}Sr/^{86}Sr)$_i$ ratios. An area of low δ^{18}O and (^{87}Sr/^{86}Sr)$_i$ is present around Glencoe (Ben Nevis–Ballachulish–Moor of Rannoch) and there is a general tendency for the granites of the southwestern Grampian Highlands and Northern Highlands to have slightly lower δ^{18}O values than those of the Southern Uplands and northeastern Grampian and Northern Highlands. Furthermore, no correlation is observed between either δ^{18}O or (^{87}Sr/^{86}Sr)$_i$ with distance from the 'Iapetus' suture in the Southern Uplands as proposed by Brown and Hennessy[15].

Magmas derived from the mantle or a primitive (basic or ultrabasic) mantle-derived source have a characteristic isotopic composition: $\delta^{18}\text{O} = 6.0\pm0.5$‰ (refs. 16, 17) and (^{87}Sr/^{86}Sr)$_i$ = 0.703±0.001 (ref. 18). Fractional crystallisation of a magma may cause slight ^{18}O enrichment, but should not affect the ^{87}Sr/^{86}Sr ratio. However, crustal processes such as weathering, hydrothermal alteration, and metamorphism can produce substantial changes in oxygen isotopic composition. Additionally, the crust has developed a high ^{87}Sr/^{86}Sr ratio because of the time-dependent effect of its generally higher Rb/Sr ratios. As a result, the crust is enriched in both ^{18}O and ^{87}Sr relative to the mantle and therefore it should be possible to recognise granites produced by crustal melting from those generated in the mantle or lower crust on the basis of their O and Sr isotopic composition. The degree to which a crystallised granite will reflect the

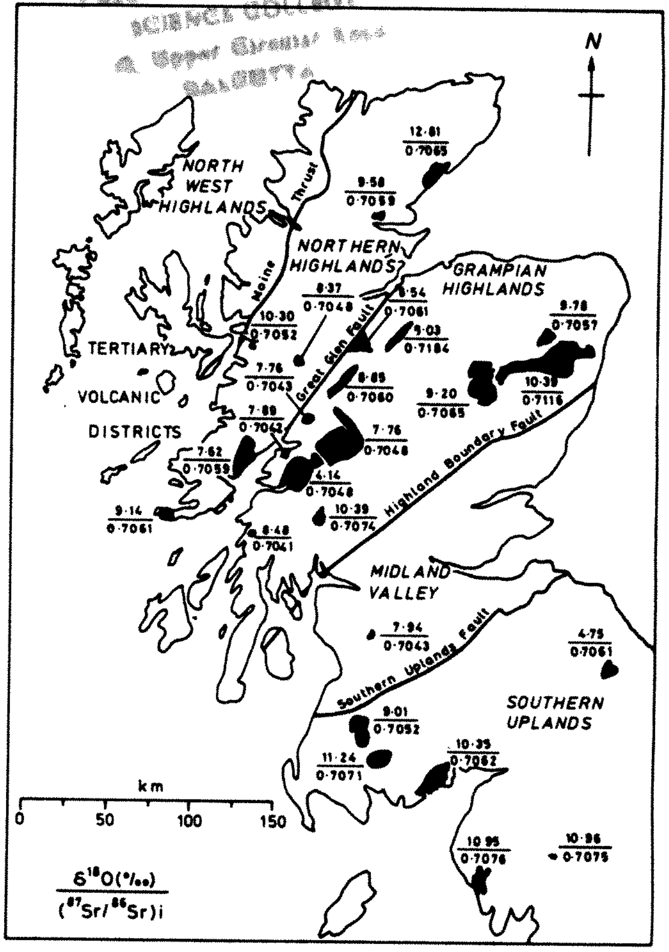

Fig. 1 Location map showing the physiographical provinces and major tectonic features of northern England and Scotland, the geographical distribution of the 'granites' sampled in this study, and the average δ^{18}O values and initial Sr isotope ratios for each pluton. The proposed 'Iapetus' suture line is considered to trend NE–SW across the Southern Uplands in the vicinity of the Solway Firth.

exact oxygen isotopic composition of the source(s) will depend on several factors, among them the temperature of melting, the degree of partial melting, the degree of volatile loss from the melt, the amount of fractional crystallisation, and the extent of post-emplacement alteration. For example, the extreme ^{18}O enrichment observed in the Tuscan Igneous Province (δ^{18}O = 11 to 17‰)[19] and the high initial ^{87}Sr/^{86}Sr ratios characteristic of the ~460-Myr-old Caledonian granites (>0.71)[4] can only be explained in terms of fusion of large amounts of crustal material. On the other hand, ^{18}O depletion can result from post-emplacement interaction with meteoric fluids or by partial fusion of materials previously affected by such a process. The ^{18}O depletion of 5 to 10‰ observed within 2 to 3 stock diameters of most intrusive centres within the Scottish Tertiary Volcanic District[20,21] is typical of such post-emplacement subsolidus exchange.

In Fig. 2 the O and Sr isotopic data for the 25 plutons are shown in histogram form. The samples analysed were, in part, those previously studied by Pidgeon and Aftalion[7] and Halliday *et al.*[5,9] for their U–Pb zircon and Rb–Sr isotopic systematics and thus do not represent a statistically valid sampling of the 'Newer' granites because, in certain instances, multiple samples were taken from individual plutons and, in others, from single outcrops (Table 2). Variations in δ^{18}O and (^{87}Sr/^{86}Sr) are observed in many of these plutons so that it is difficult to represent the isotopic composition of an intrusion by a single sample[9]. Therefore, in cases for which more than one sample was analysed from a single location (such as Bonar Bridge) or for which the initial Sr isotope ratio was derived from a whole-rock isochron regression on a suite of samples from a particular pluton (such as Lochnagar), only a single, averaged δ^{18}O and (^{87}Sr/^{86}Sr) value for that pluton has been plotted in Fig. 2. Otherwise, where more than one outcrop of a particular pluton was sampled (as for Doon), each data point is shown.

The large range in both δ^{18}O values (4.1–14.4‰) and (^{87}Sr/^{86}Sr)$_i$ ratios (0.7037–0.7184) is apparent. No correlation is observed between either isotopic parameter and emplacement age or intrusion style, except that the two plutons with extremely high (^{87}Sr/^{86}Sr)$_{400}$ ratios (Findhorn and Aberdeen) may be significantly older than the other granites sampled. Although the ages for these two plutons are uncertain, their Rb/Sr ratios are sufficiently low that this does not nullify their distinctively high initial Sr isotopic ratios. Substantial within-pluton variation in both δ^{18}O and (^{87}Sr/^{86}Sr)$_i$ coincident with compositional trends are observed for those composite plutons studied in detail (Table 1).

No significant differences are observed for either isotopic parameter between the forceful and permitted granites sampled except that the two samples with anomolously low δ^{18}O values Cheviot and Ben Cruachan, are both high-level probably sub volcanic, 'Last' granites. The ^{87}Sr/^{86}Sr initial ratios for Moor of Rannoch and Ballachulish (forceful 'Newer' granites) are effectively identical to those of Ben Nevis and Ben Cruachan (passive 'Last' granites). Thus, the recent suggestion by Brown and Locke[22] on the basis of recent trace element and geophysical studies[23–25] that the 'Older' granites, as defined by Read[6], and the forceful 'Newer' granites are genetically related and largely derived from continental crust whereas the passive 'Last' granites were derived largely from the mantle is incompatible with the isotopic data presented here and the important isotopic work of Pankhurst[26] on the Strontian and Foyers granites.

The generally low (^{87}Sr/^{86}Sr)$_i$ ratios and extremely variable ^{18}O/^{16}O ratios observed preclude an origin of the forceful 'Newer' granites simply by partial fusion of highly evolved crustal materials as detailed by Pankhurst[4] and Bell[27] for the 'Older' granites and ~460-Myr-old Aberdeenshire granites. Rather, we consider the 'Newer' and 'Last' granites to comprise a distinct magmatic group, as first proposed by Read[6], which were chiefly formed between ~435 Myr and 390 Myr and that the observed field differences are related to a time-variable local tectonic setting rather than being a genetic characteristic of the granites themselves.

Of particular interest are the two samples which show extremely low δ^{18}O values of <5‰ (Ben Cruachan and Cheviot). These two ^{18}O/^{16}O ratios which represent the first recorded occurrence of pre-Tertiary low-^{18}O granites in the British Isles, are clearly anomalous within the context of the other Late Caledonian granites sampled. Their oxygen isotopic composition can only be explained in terms of either post-emplacement exchange between the granite plutons and ^{18}O-depleted meteoritic groundwater or a derivation from partial fusion of pre-existing low-^{18}O crustal rocks. (^{87}Sr/^{86}Sr)$_i$ ratios for the two samples show no major enrichment with radiogenic Sr as would be expected if they had originated from a crustal source (Ben Cruachan = 0.7048; Cheviot = 0.7061). Pankhurst *et al.*[28] have shown that Sr isotope ratios are not necessarily affected during hydrothermal interaction which has resulted in substantial ^{18}O depletion. Although Forester and Taylor[20,21] have documented that the southern porphyritic epigranite of the Tertiary Red Hills complex, Skye was intruded as a low-^{18}O magma derived from the partial melting of altered metasediments, we favour a post-emplacement cause because both are high-level, subvolcanic centres where the effects of such hydrothermal processes are most likely to be present.

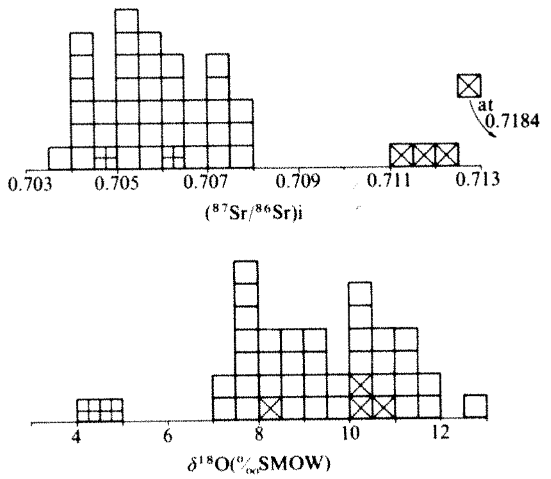

Fig. 2 Histograms of δ^{18}O and (^{87}Sr/^{86}Sr)$_i$ for the 'granites' sampled. The two low-^{18}O samples (Cheviot and Ben Cruachan) are indicated by vertical crosses and the extremely ^{87}Sr-enriched samples of uncertain age (Findhorn and Aberdeen) by diagonal crosses.

It is also seen from Fig. 2 that approximately one quarter of the granites sampled have δ^{18}O values which lie within Taylor's[16] I and H$_{\rm I}$ groups for plutonic igneous rocks. Although the oxygen isotopic composition of these granites is compatible with a mantle or primitive mantle-derived source, allowing for a 1 to 1.5‰ enrichment in ^{18}O during fractional crystallisation, their initial strontium isotope ratios require that the magmas had to some extent interacted with continental crust during their evolution. Previous O-, Sr-, and Pb-isotopic studies have recognised the involvement of crustal materials in the production of granitic magmas[4,7,16,29–32]. However, the exact nature and degree of this involvement remains unclear. Chappell and White[12] and O'Neil and Chappell[33] have pointed out that it may be possible to recognise granitic rocks derived primarily from metasedimentary crustal sources (S type) and those with primitive igneous origins (I type) on the basis of their petrologic, chemical and isotopic compositions. As regards the Caledonian granites, Pankhurst[26] has pointed out that there is a clear distinction between 'Older' and 'Newer' granites. The 'Older' suite is comprised of small, two-mica granites which have low Ca and Na/K with high (^{87}Sr/^{86}Sr)$_i$, a predominance of biotite over hornblende, and true granitic compositions; all characteristics of an S type affinity. By contrast, the 'Newer' and 'Last' granites are generally large, complex and often composite plutons ranging from diorite to granite in composition, with hornblende, and high Ca and Na/K with low $(^{87}Sr/^{86}Sr)_i$. This would suggest that these late Caledonian granites should be predominantly of I type, but such a categorical classification is not supported by our O and Sr isotopic data.

Relationship between oxygen and strontium isotope ratios

Figure 3 is a plot of $\delta^{18}O$ against $(^{87}Sr/^{86}Sr)_i$ for the 25 granites analysed. The two low-^{18}O samples (Ben Cruachan and Cheviot) and the two extremely ^{87}Sr-enriched samples (Findhorn and Aberdeen) have been omitted. The compositional trends previously described are clearly illustrated. Both $\delta^{18}O$ and $(^{87}Sr/^{86}Sr)_i$ tend to increase sympathetically with the progression from more mafic to more felsic compositions. The $\delta^{18}O$ values for this group of late Caledonian granites as a whole appear to form a continuous distribution across the S–I boundary of ~10‰ suggested by O'Neil and Chappell[33] and O'Neil *et al.*[34] for the Australian Palaeozoic granites with no tendency for the forceful 'Newer' granites to be more S type in nature than the passive 'Last' granites.

The most important feature of Fig. 3 is the positive correlation between $\delta^{18}O$ and $(^{87}Sr/^{86}Sr)_i$ which is statistically significant ($r^2 = 0.75$) at the 99% confidence level. That this trend is parallel to that observed by Taylor and Silver[2] for the Peninsular Ranges batholith of California and Baja would strongly imply that a fundamental petrogenetic process must be responsible for the sympathetic O and Sr isotope variation observed. Differential partial melting of a single source or derivation from a single partial melt at each site are effectively ruled out by the large oxygen isotope variations observed within and between individual plutons. Incidentally, a major difference between the British Caledonides and California/Baja is the striking geographical effects observed in the isotopic systematics of the latter[2], which is probably due to its simpler geology setting and history.

It is also noteworthy that positive correlations of $(^{87}Sr/^{86}Sr)_i$ with Rb/Sr are observed for the late Caledonian granites which is also suggestive of magma mixing. Halliday *et al.*[5] have considered possible sources for an upper crustal component: Lewisian, Moinian and Dalradian metamorphic rocks and Lower Palaeozoic sediments. Whilst all fulfill the requirements imposed by the granite U–Pb zircon systematics, the Southern Uplands Lower Palaeozoic sediments are the only abundant upper crustal material that could provide a melt derivative of the required Sr isotopic composition. An oxygen isotopic study of these sediments[9], the result of which is shown in Fig. 3, indicates that such material would be suitable upper crustal end member composition for the magma mixing situation we envisage for the late Caledonian granites. For example, the Shap and Eskdale

* Strontium isotope initial ratios calculated assuming 400 Myr age, but may be older.

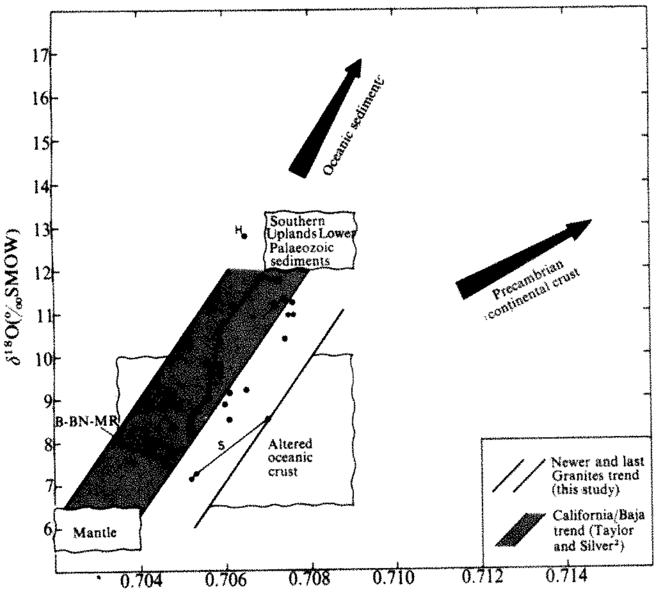

Fig. 3 $\delta^{18}O$–$(^{87}Sr/^{86}Sr)_i$ relationships for the 'granites' sampled. Not shown are the data for Cheviot, Ben Cruachan, Findhorn and Aberdeen. Isotopic variations corresponding to compositional trends are shown for the 'forceful' granites—Strontian and Criffell. The point indicated by 'H' is the Helmsdale granite and the B–BN–NR field is that for the Ballachulish, Ben Nevis and Moor of Rannoch granites. The shaded trend within the 'Newer Granites' trend is that observed by Taylor and Silver for the Peninsular Ranges batholith in California and Baja. For reference the fields of 'Mantle', 'Altered Oceanic Crust' and 'Southern Uplands Lower Palaeozoic Sediments' are shown together with postulated mixing trends between 'Mantle' and 'Precambrian Continental Crust' and 'Mantle' and 'Oceanic Sediments'.

granites of the Lake District and Fleet of the Southern Uplands plot with high $\delta^{18}O$ and $(^{87}Sr/^{86}Sr)_i$ and lie close to the field of Southern Uplands Lower Palaeozoic sediments shown in Fig. 3. The 'sedimentary' nature of these granites is clear and the conclusion must be drawn that they were largely derived from the geosynclinal metasedimentary wedge in which they occur. However, such sediments do not outcrop north of the Highland Boundary Fault, and even if underthrust during subduction, neither these geosynclinal sediments nor a severely altered oceanic basaltic slab could provide the inherited U–Pb component observed in zircons for granites north of the fault[5,9]. Some clues as to the nature of the crustal component have been provided by recent Pb isotope studies[13] from which it is apparent that a comparatively non-radiogenic Pb component is present in some of the Caledonian granites of the Northern Highlands (for example, Foyers and Ross of Mull). This evidence strongly suggests at least partial derivation of the Northern granites from an old, U-depleted crustal source such as Lewisian granulites. Nevertheless, both the Pb isotope data and the difficulty of extracting large volumes of 'granitic' magmas from granulites further support our contention that mantle or 'new' basic lower crust was also involved in the production of the late Caledonian granites. The large variations in both $^{18}O/^{16}O$ and $(^{87}Sr/^{86}Sr)_i$ ratios observed within single plutons (Fig. 3) together with the absence of U–Pb memory in the zircons of the Strontian tonalite contrasted with a marked inherited U–Pb component in the Strontian biotite granite[5,7] endorse this view. Pankhurst[26] has suggested on the basis of trace element and isotopic data that basaltic lower crust is a more likely candidate than mantle peridotite for the low-$^{87}Sr/^{86}Sr$ end member.

Discussion

It thus seems that each of the late Caledonian granites we have studied was derived from a variable mixture of mantle and/or basic lower crust and more isotopically evolved continental material analogous to the local upper crust. Further speculation is difficult because at present there are no oxygen isotope data on Precambrian crustal rocks of Britain other than the unpublished work of Kay[35]. The high $^{87}Sr/^{86}Sr$ ratios of all major Precambrian rock types (Lewisian, Moinian, Dalradian)[5] suggests that such a crustal melt would plot in Fig. 3 with a higher $^{87}Sr/^{86}Sr$ initial ratio for a given $\delta^{18}O$ value than the Southern Uplands Lower Palaeozoic sediments and thus not lie on the required mixing line to produce the general $\delta^{18}O$–$(^{87}Sr/^{86}Sr)_i$ trend observed. However, the partial melting of such ^{87}Sr-enriched Precambrian rocks may be locally important. This would provide an explanation for the tendency of the Strontian data to plot with lower slope than that of Criffell (Fig. 3). It is almost certain that more detailed studies of individual intrusions, such as that recently completed for the three Southern Uplands granites Doon, Criffell and Fleet[9], will reveal that the overall trend observed in Fig. 3 is comprised of a suite of correlations within the observed limits which relate to the local geological environment.

The model we envisage to explain the isotopic variations observed for the late Caledonian granites involves progressive upward melting from the mantle such that the first magma emplaced is derived from the most primitive source. The rise of granodioritic/tonalitic magma results in the transfer of heat to the surrounding crust sufficient to mobilise acidic melts at high levels in the crust. In some instances successive emplacement of more felsic magmas occurred in discrete pulses after hybridisation, whilst in others the magma pulses became progressively enriched in the crustal component. Simple modelling in a two-component system suggests that between 30 and 80 wt% of crustal contamination is required to account for the observed O and Sr isotopic variations.

This work is a continuation of a large-scale isotopic reconnaissance study of British granites begun by R. T. Pidgeon. We thank Professor H. W. Wilson for his support, J. Borthwick, J. Hutchinson and J. Jocelyn for technical assistance in the laboratory, and M. L. Coleman, S. M. F. Sheppard, W. E. Stephens, L. T. Silver, H. P. Taylor, P. E. Brown, C. Graham, I. Munro and A. Rickard for samples and discussion. The Isotope Geology Unit at SURRC is supported by a grant from NERC. Manuscript typed by Mrs A. McCartney.

E. coli recA protein-directed cleavage of phage λ repressor requires polynucleotide

Nancy L. Craig & Jeffrey W. Roberts

Department of Biochemistry, Molecular and Cell Biology, Wing Hall, Cornell University, Ithaca, New York 14853

The recA protein mediates both genetic recombination and several cellular responses to DNA damage, including the induction of temperate bacteriophage. Induction of phage λ results from proteolytic cleavage of λ repressor directed by recA protein. We show here that this cleavage reaction requires both polynucleotide and ATP. We suggest that a stoichiometric complex of recA protein and DNA is active both to destroy repressors by proteolytic cleavage and to initiate pairing of this DNA to its homologous sequence in a DNA duplex ('strand invasion').

THE product of the *recA* gene of *Escherichia coli* appears to have two distinct roles; it is required for all pathways of general genetic recombination[1] and it regulates the expression of several important cellular processes, sometimes called the SOS functions, which are induced when cellular DNA is damaged or its replication is obstructed[2,3]. These processes include the development of temperate bacteriophage, the expression of colicinogenic plasmids[4], an inhibition of cell division that leads to filamentation, and an error-prone DNA repair capacity that is an important source of radiation and chemical mutagenesis. Furthermore, recA protein regulates its own expression: its rate of synthesis is greatly increased by inducing treatments, but this amplification requires *recA* function[5-7].

How does recA protein mediate these different processes? We suggest that it has two separate biochemical activities, which are related by the interaction of recA protein with DNA that we describe in this article. Others have shown that purified recA protein catalyses the pairing of homologous DNA strands, an activity that accounts for its direct role in genetic recombination[8-11]. We have shown that recA protein inactivates the repressors of phages λ and P22 *in vitro* by proteolytic cleavage, a finding that explains the role of *recA* function in phage induction[12-14]. This activity of recA protein to inactivate or modify proteins by proteolytic cleavage may underlie its regulatory function in the expression of other *recA*-dependent processes as well. One specific regulatory role of the proteolytic activity may be to promote the amplification of recA protein itself: the *lexA* gene product, thought to be repressor of the *recA* gene[15], could be inactivated by recA protein present at a low basal level before induction, thus causing depression of the *recA* gene[5-7].

Table 1 Rate of recA protein dependent cleavage of λ repressor in the presence of various polynucleotides

Polynucleotide	Polynucleotide concentration (μg ml^{-1})	Rate of cleavage (ng per min per μg recA protein) Low salt (0.06 M)	High salt (0.18 M)
1. None	—	<0.1	<0.1
2. Denatured λ DNA	1.5	38	12
3. Native plasmid DNA	22	7.2	0.3
4. poly(rA)	1.0	50	19
5. poly(dT)	1.5	43	10
6. $(dA)_{16}$	6.0	25	4.0
7. $(dT)_9$	20	25	4.9

Reaction mixtures of 20 μl were prepared as described in Fig. 1, using 1 mM ATP-γS, 2 mM $MgCl_2$, 3.4 μg repressor, 0.6 μg recA protein, polynucleotide as indicated, and salt as indicated. 'Low salt' was 0.015 M NaCl and 0.045 M KCl; 'high salt' was 0.135 M NaCl and 0.045 M KCl. After incubation for 45 min at 37 °C (low salt reaction) or 2 h at 37 °C (high salt reaction) cleavage was determined as described in Fig. 3. Homopolymers and oligonucleotides were obtained from P–L Biochemicals. Plasmid DNA was a derivative of pMB9, made linear by digestion with *Eco*RI endonuclease followed by phenol extraction.

We show here that the activity of purified recA protein to direct cleavage of phage λ repressor requires both polynucleotide and ATP. recA protein also associates with single-stranded DNA in the set of ATP-depenendent reactions that lead to pairing of this DNA to its homologous sequence in a DNA duplex ('strand invasion')[8,10,11]. We suggest that in the presence of ATP, recA protein binds in a stoichiometric complex with single-stranded DNA, and is thereby activated both to attack repressors and to engage in DNA strand pairing.

Repressor cleavage depends on ATP and polynucleotide

We have reported that purified recA protein promotes the specific proteolytic cleavage of purified λ repressor into two fragments, in a reaction that requires ATP and small molecules[12,13]. The requirement for polynucleotide originally was obscured by the presence of a contaminating polynucleotide synthetic activity in recA protein prepared as we previously described. Because this activity is inhibited by inorganic phosphate and because it sediments at about 9S (data not shown), it is probably polynucleotide phosphorylase, which utilises ADP derived from ATP to synthesise polyriboadenylic acid[16]. The experiment of Fig. 1 shows that λ repressor cleavage directed by highly purified recA protein is dependent on both ATP and polynucleotide, here denatured λ DNA. The ATP analogue ATP-γS[20] substitutes effectively for ATP and supports a several-fold higher rate of cleavage than does ATP. For this and all experiments reported here we used recA protein prepared from cells carrying the *recA* mutation tif^- (ref. 15), although we obtained qualitatively similar results using recA protein from tif^+ cells.

A variety of single-stranded polynucleotides support the cleavage of repressor by recA protein; native DNA is much less effective, particularly in reactions at higher salt concentrations (Table 1). Other polynucleotides that are active include denatured DNA restriction fragments several hundred nucleotides long, single-stranded DNA of phage G4, poly (rC) and poly(U) (data not shown). We also have detected cleavage in the presence of oligonucleotides as short as six nucleotides in the ATP-γS dependent reaction (data not shown). The finding that poly(rA) stimulates cleavage supports our suggestion that less purified *recA* fractions lack the polynucleotide requirement because poly(rA) is synthesised during the cleavage reaction. Because homopolymers are active, the formation of double-stranded polynucleotide[9] is not essential to the reaction.

0028-0836/80/010026—05$01.00

The rate of repressor cleavage in the ATP-γS stimulated reaction is approximately constant for several hours (Fig. 2). In optimal conditions (Table 1) the rate of repressor cleavage is 40–50 ng repressor per min per μg recA protein; ATP provides about one-fourth this rate. Thus recA protein promotes cleavage of an equimolar amount of repressor in about 15 min in these conditions. Both recA protein and represssor are present at concentrations that limit the rate of this reaction[14]. From the experiment of Fig. 3, track *a*, it can be seen that recA protein functions catalytically: 0.9 μg recA protein directed cleavage of 6 μg repressor, representing a turnover of 10 repressor monomers (molecular weight (MW) 26,000) per recA monomer (of MW 40,000). Figure 3, track *c* demonstrates that essentially all of the input repressor is sensitive to recA protein directed cleavage.

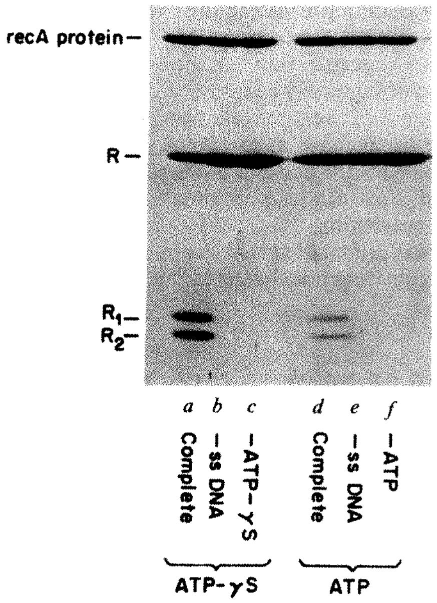

Fig. 1 Dependence of the recA protein directed cleavage of λ repressor on polynucleotide and ATP or ATP-γS. Reaction mixtures of 30 μl contained 13 mM Tris HCl *p*H 7.5, 1 mM potassium phosphate, 0.55 mM EDTA, 0.4 mM $CaCl_2$, 2.4 mM dithiothreitol, 0.145 M NaCl, 0.015 M KCl, 5% (w/v) sucrose, 4% (v/v) glycerol, 0.9 μg recA protein, 3.2 μg λ repressor, and 1.3 μg ml^{-1} heat-denatured λ DNA (unless omitted). Reactions *a–c* contained in addition 2 mM $MgCl_2$ and 1 mM ATP-γS (unless omitted); reactions *d–f* contained in addition 10 mM $MgCl_2$ and 5 mM ATP (unless omitted). Track *a*, complete reaction (ATP-γS); track *b*, DNA omitted; track *c*, ATP-γS omitted; track *d*, complete reaction (ATP); track *e*, DNA omitted; track *f*, ATP omitted. After incubation for 60 min at 37 °C reaction mixtures were analysed by SDS-gel electrophoresis[12] and staining with Coomassie brilliant blue. Bands corresponding to recA protein, λ repressor, and both fragments derived from λ repressor are indicated[12]. *tif*⁻-recA protein was prepared from *E. coli* DM1187 as described in ref. 13 with the following changes. The ammonium sulphate pellet obtained by fractionating the polymin P eluate was extracted with buffer to which 0.20 g ml^{-1}, ammonium sulphate was added; after centrifugation, protein was precipitated from the supernatant by addition of 0.15 g ammonium sulphate per ml. After dialysis, this protein was chromatographed on DNA-agarose, or on phosphocellulose, or on phosphocellulose in 20 mM potassium phosphate, *p*H 6.5, 0.1 mM EDTA, 1 mM dithiothreitol, and 10% (v/v) glycerol, eluting with a gradient of KCl to 0.25 M in the same buffer[9]. Usually we used two cycles of phosphocellulose chromatography, or DNA-agarose followed by phosphocellulose. The peak of protein was concentrated with ammonium sulphate and centrifuged on a sucrose gradient as described in ref. 13, except that the gradient was collected from the top to avoid contamination with polynucleotide phosphorylase, which sediments faster than recA protein. The protein appeared homogeneous by gel electrophoresis in SDS. The main criterion for purity was complete dependence on added polynucleotide for repressor cleavage, a condition that correlated with very low or undetectable activity of polynucleotide phosphorylase. Phosphate was added to reaction mixtures to inhibit any residual polynucleotide phosphorylase. There was no detectable endonuclease active on denatured λ DNA in either recA protein or λ repressor. λ repressor was prepared from *E. coli* 294 (pKB277) (ref. 17) by the following modification of the method of Sauer and Anderegg[18]. Cells were grown in medium containing 16 g tryptone, 10 g yeast extract, and 5 g NaCl per litre to an A_{550} of 1. After fractionation of the crude extract with polymin P and ammonium sulphate, protein was loaded onto a single stranded DNA-agarose column prepared as described by Schaller *et al.*[19], in a buffer containing 10 mM Tris HCl *p*H 7.9, 1 mM EDTA, 2 mM $CaCl_2$, 3 mM dithiothreitol, 5% glycerol (v/v), and 0.1M KCl. Protein was eluted with the same buffer containing 0.4 M KCl, chromatographed on hydroxylapatite[13], concentrated with ammonium sulphate, and centrifuged on a 10–30% (v/v) glycerol gradient in the above buffer containing 10 mM dithiothreitol and 0.2 M KCl for 40 h at 35,000 r.p.m. in the Beckman SW41 rotor. Sometimes the centrifugation was repeated to remove traces of polynucleotide phosphorylase. λ DNA, prepared by phenol extraction, was denatured by heating for 5 min at 100 °C, followed by rapid chilling. ATP-γS was obtained from Boeheringer.

A parenthetical, but important point is that the further purification of recA protein does not separate from it any factors required for repressor cleavage. Thus we presume that recA protein is the protease, although we lack a rigorous proof that recA protein does not act in concert with a protease present in trace amounts that we cannot detect separately. We can conclude that recA protein is directly required for the reaction, because variants of recA protein prepared from mutants display different activities for repressor cleavage *in vitro* (refs 12, 13 and unpublished experiments).

The polynucleotide requirement for repressor cleavage

Since both recA protein and λ repressor are DNA-binding proteins, either or both might interact with polynucleotide in repressor cleavage. The following results suggest that the primary interaction of polynucleotide is with recA protein.

Polynucleotide-dependent ATPase activity of recA protein: Purified recA protein has a polynucleotide-dependent ATPase activity; its dependence on single-stranded DNA is shown in Fig. 4. The characteristics of this ATPase suggest that the same interaction of polynucleotide and ATP with recA protein activates both ATPase and the repressor cleavage reaction. All single-stranded polynucleotides that stimulate repressor cleavage (Table 1) also stimulate the ATPase, except the two oligonucleotides. (These oligonucleotides stimulate repressor cleavage with ATP-γS, but not detectably with ATP; data not shown.) Native DNA is severalfold less effective than denatured DNA in stimulating the ATPase in these conditions (data not shown).

The ATP analogue ATP-γS, which substitutes effectively for ATP in repressor cleavage, is not hydrolysed by recA protein; in

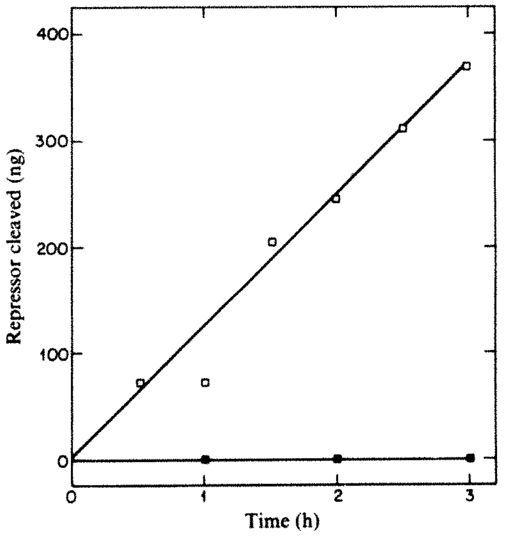

Fig. 2 Time course of λ repressor cleavage. Reaction mixtures of 20 μl were prepared as described in Fig. 1, but containing 0.14 M NaCl, 0.045 M KCl, 2 mM $MgCl_2$, 1 mM ATP-γS, 0.5 μg recA protein, 4.1 μg λ repressor, and 1.4 μg ml^{-1} denatured λ DNA (unless omitted). After incubation reaction mixtures were analysed by SDS gel electrophoresis and staining with Coomassie brilliant blue. The amount of repressor cleaved was measured by densitometric tracing of fragments R_1 and R_2, using as a standard repressor fragments from a reaction mixture in which a known amount of repressor was completely cleaved (as in Fig. 3*c*). ■, DNA omitted; □, complete reaction.

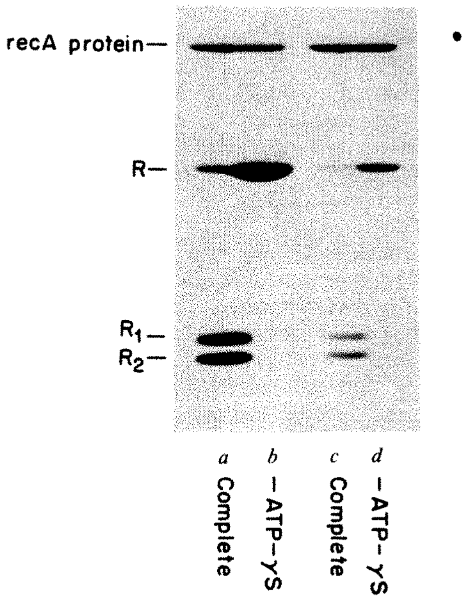

Fig. 3 Efficiency of λ repressor cleavage. Reaction mixtures of 30 μl were prepared as described in Fig. 1, except that they contained 2 mM $MgCl_2$, 1 mM ATP-γS (unless omitted), 0.9 μg recA protein, 1.3 μg ml^{-1} denatured λ DNA and λ repressor as given. After incubation for 5 h at 37 °C, reaction mixtures were analysed as in Fig. 1. Track *a*, complete reaction with 8.4 μg λ repressor; track *b*, as track (*a*), but ATP-γS omitted; track *c*, complete reaction with 1.4 μg λ repressor; track *d*, as track *c*, but ATP-γS omitted.

fact, it is a potent inhibitor of both the ATPase activity (Fig. 4) and the strand invasion reaction[10,11,13]. A reasonable interpretation of these facts is that binding alone of either nucleotide to a site on recA protein in the presence of polynucleotide activates repressor cleavage, whereas hydrolysis of ATP is required for strand invasion. It is consistent with this proposal that for both repressor cleavage and ATPase, ATP is required at a relatively high concentration and ATP-γS is effective at a relatively low concentration. ATP is required at ~1 mM to stimulate repressor cleavage, near its K_m for the ATPase reaction (~0.5 mM) (data not shown). ATP-γS inhibits the ATPase reaction in the micromolar concentration range (Fig. 4), at which it is also effective in supporting repressor cleavage.

Polynucleotide concentration dependence of repressor cleavage: The rate of recA protein-directed cleavage of repressor depends on the concentration of polynucleotide in the reaction mixture. When ATP-γS is used, there is a striking polynucleotide concentration optimum. Figure 5 shows a polyacrylamide gel analysis of reaction mixtures incubated with increasing concentrations of single-stranded DNA. In control experiments, we found the rate of repressor cleavage to be constant during this incubation, so that we can infer the rate of cleavage from the final yield of repressor fragments R_1 and R_2 (see Fig. 2). It is apparent that a maximum rate is reached as the concentration of DNA is increased and that higher concentrations sharply inhibit the reaction. Single-stranded DNA of phage G4, poly(rA), and poly(dT) yield similar concentration optima and maximum cleavage rates. The optimum for duplex DNA is much broader and occurs at a higher DNA concentration. When ATP is used instead of ATP-γS, the concentration optimum for single-stranded polynucleotide is the same, but the inhibition by higher concentrations is less pronounced.

The nature of the DNA concentration dependence of repressor cleavage suggests that the polynucleotide interacts with recA protein: both the maximum rate of cleavage and the DNA concentration at which this maximum occurs vary with the concentration of recA protein. To show this, we have constructed DNA dose curves similar to that in Fig. 5, using three different concentrations of recA protein. From this experiment (Fig. 6) we draw three conclusions:

(1) The DNA concentration optimum is approximately proportional to the recA protein concentration. Thus with 15, 30 and 60 μg ml^{-1} recA protein, the respective DNA concentration optima are about 0.8, 1.5 and 3 μg ml^{-1}. Taking 40,000 and 330 as the molecular weights of a recA monomer[6] and a nucleotide of DNA, we calculate that the maximum rate of cleavage occurs with six nucleotides per recA monomer. (The major uncertainty in this calculation is the concentration of recA protein, which we estimated by assuming an extinction coefficient of 1.0 mg^{-1} ml^{-1} at 280 nm.)

(2) At a DNA concentration less than the optimum, the rate of cleavage is approximately proportional to DNA concentration and independent of recA protein concentration.

(3) The rate of cleavage at the DNA optimum increases with recA protein concentration; for the two higher concentrations of recA protein, this rate is approximately proportional to recA protein concentration.

In similar experiments we have found that the DNA concentration optimum does not change as the repressor concentration is varied.

The active complex of recA protein and DNA

Because the greatest rate of repressor cleavage occurs at a constant ratio of recA protein to DNA for various concentrations of recA protein, we infer that these components form a stoichiometric complex in the presence of ATP or ATP-γS that is active in cleavage. Others have suggested that recA protein binds DNA tightly in the presence of these nucleotides[10,11]. A reasonable presumption is that binding to polynucleotide causes a conformational shift in recA protein to a form that is active to bind and cleave repressors. In this model, the function of ATP or ATP-γS in repressor cleavage might be to promote the formation of the active complex of recA protein and polynucleotide. The repressor also could contact polynucleotide during the cleavage reaction, but we have no information about this possibility.

It seems likely that the recA protein–DNA complex active in repressor cleavage is the same that is active in the strand

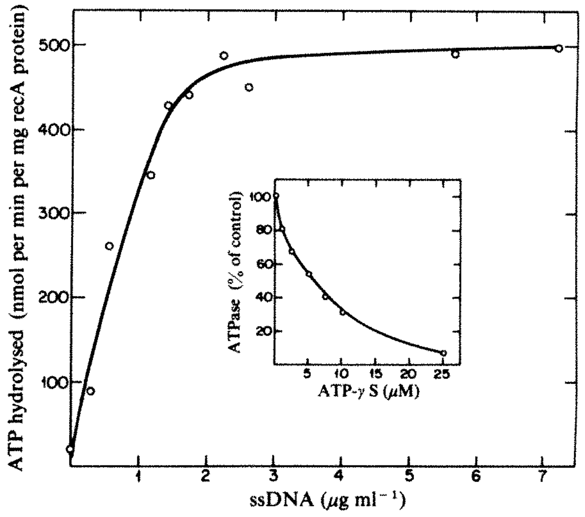

Fig. 4 DNA-dependent ATPase activity of recA protein. (Inset: inhibition of recA ATPase by ATP-γS). Reaction mixtures contained 11 mM Tris-HCl, *p*H 7.5, 0.18 M NaCl, 10 mM $MgCl_2$, 0.5 mM dithiothreitol, 0.35 mM EDTA, 5 mM [γ-^{32}P]ATP, 6.5% (w/v) sucrose, 29 μg ml^{-1} recA protein, and denatured λ DNA as indicated. After an incubation of 15 min at 37 °C, ATP hydrolysis was determined by the method of Avron[22]. Inhibition by ATP-γS was measured in reaction mixtures as above, but containing 27 μg ml^{-1} recA protein, 68 μg ml^{-1} denatured DNA, 1.5 mM [γ-^{32}P]ATP, and ATP-γS as indicated; ATP hydrolysis was determined after an incubation of 30 min at 37 °C.

Fig. 5 Effect of single-stranded DNA concentration on repressor cleavage. Reaction mixtures of 20 µl were prepared as described in Fig. 1, except that they contained 0.14 M NaCl, 0.04 M KCl, 2 mM KCl (ref. 2), 1 mM ATP-γS, 0.5 µg recA protein, 3.7 µg λ repressor, and denatured λ DNA as indicated. After incubation for 2 h at 37 °C reaction mixtures were analysed by SDS-gel electrophoresis and staining with Coomassie brilliant blue. Track *a*, no DNA; tracks *b–u*, 0.2, 0.3, 0.4, 0.6, 0.8, 1.2, 1.4, 1.5, 1.7, 1.9, 2.2, 2.5, 2.6, 3.0, 3.5, 4.3, 5.0, 5.7, 7.2 and 9.5 µg ml^{-1} DNA.

invasion reaction. Shibata *et al.*[8] have determined an optimum ratio of one recA monomer to five nucleotides of single-stranded DNA to catalyse invasion of this strand into duplex DNA to form a D-loop; this is identical within experimental error to our calculated optimum of six nucleotides per recA monomer for the repressor cleavage reaction. Furthermore, D-loop formation also is inhibited if DNA is present in excess over the apparent stoichiometric value[8,10]. An obvious difference between the reactions is that ATP-γS promotes repressor cleavage but not D-loop formation. However, Cunningham *et al.*[11] have shown that ATP-γS does stimulate recA protein to melt duplex DNA in the presence of single-stranded DNA. Thus recA protein is activated both for repressor cleavage and for this initial step of strand invasion by interaction with single-stranded DNA and ATP-γS. (Presumably ATP hydrolysis is required for a subsequent step of strand invasion.)

We do not know why excess DNA inhibits the cleavage and strand pairing activities of recA protein. We note that inhibition of repressor cleavage by excess DNA is most striking in the presence of the ATP analogue ATP-γS, which is not hydrolysed, and that the ATPase activity of recA protein is not inhibited by high concentrations on DNA. One possibility is that excess DNA interacts with a second site of recA protein normally utilised in the strand pairing reaction, and that this interaction locks the protein into an inactive form when the non-hydrolysable analogue is present. As excess single-stranded DNA also inhibits strand invasion, it probably affects recA protein rather than repressor.

Regulation of recA protein activity *in vivo*

A lysogen is induced by treatments that damage cellular DNA, leading to cleavage and inactivation of repressor by recA protein. We have described conditions in which recA protein cleaves λ repressor *in vitro*. How is this activity of recA protein regulated to cause induction? The presence of wildtype recA protein in the cell is not sufficient to cause repressor inactivation *in vivo*. Instead, it is likely that a signal invoked by damage to cellular DNA activates recA protein to cleave repressors[5-7,23]. This activation also is thought to cause amplification of recA protein: by hypothesis, the inducing signal stimulates a small amount of recA protein present before induction to cleave a repressor of the *recA* gene, encoded by the *lexA* gene, leading to amplification of the recA protein itself. Both the activation and the increased amount of recA protein are probably required for full expression of *recA*-dependent processes, including phage repressor inactivation.

How can we relate the requirement for a signal to activate recA protein *in vivo* to the fact that recA protein is active in our conditions *in vitro*? One possibility is that we are providing the signal, or one possible signal, by adding single-stranded DNA. Many inducing treatments (such as UV irradiation) lead to single-stranded regions ('gaps') in chromosomal DNA because replication is interrupted at lesions (such as pyrimidine dimers)[24]; such gaps could bind and activate recA protein and thus be a sufficient signal for induction. It is reasonable that recA protein should be directed to gaps, because its major DNA repair function is probably to remove such discontinuities by provoking recombination of the damaged helix with an intact sister chromatid. Alternatively, oligonucleotides resulting from degradation of damaged DNA could provide a signal to activate recA protein[23].

We doubt, however, that a polynucleotide derived from damaged DNA is the only possible signal. A mutation in the *recA* gene, named *tif*[25], alters the protein to make it active without damage to cellular DNA; it is sufficiently active at high temperature (40° C) to allow full induction of *recA*-dependent functions, and it has substantial activity at low temperature (30° C) in the absence of an inducing treatment[15]. Yet purified *tif*$^-$-recA protein, which we used in these experiments, is completely dependent on polynucleotide for repressor cleavage activity *in vitro*. What polynucleotide does *tif*$^-$-recA protein utilise *in vivo*? One possibility is duplex chromosomal DNA, since native DNA has significant activity to promote repressor cleavage *in vitro* (Table 1). Alternatively *tif*$^-$-recA protein could interact with a unique DNA structure at a growing fork or at the origin of replication[26,27]. In either case, the *tif*$^-$-recA protein might be able to utilise chromosomal DNA under conditions in which the wild type protein cannot. The fact that *tif*$^-$-recA protein appears to utilise some undamaged polynucleotide in the cell suggests a second possible type of inducing signal for recA protein: a regulatory molecule could be elaborated in induced cells that binds recA protein and allows it to interact with chromosomal DNA, so that recA protein is activated both to cleave repressors and to engage in recombination. Further study of the behaviour of recA protein *in vitro* may reveal what signal or signals activate it *in vivo*.

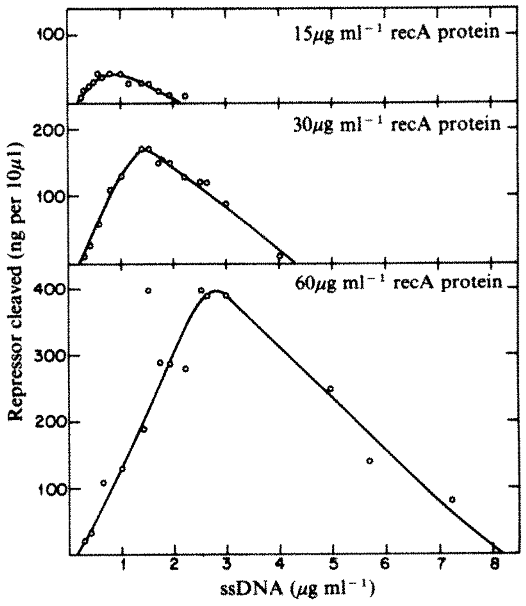

Fig. 6 DNA dependence of repressor cleavage at various concentrations of recA protein. Reaction mixtures prepared as in Fig. 1 contained 0.14 M NaCl, 0.045 M KCl, 2 mM $MgCl_2$, 1 mM ATP-γS, 120 µg ml^{-1} λ repressor, and recA protein and denatured λ DNA as indicated. After incubation for 2 h at 37 °C, reaction mixtures were subjected to SDS gel electrophoresis and cleavage was measured as described in Fig. 2.

Function of the protease activity of recA protein

The protease activity of recA protein clearly is responsible for the induction of temperate bacteriophages, and probably for induction of the *recA* gene itself. Thus it is required at least indirectly for recombinational repair of DNA, which occurs efficiently only if recA protein is amplified. Other *recA*-dependent processes such as mutagenesis might involve proteolytic modification of cellular proteins, as well as the strand pairing activity of recA protein.

Does the protease activity also have a direct role in genetic recombination? The fundamental reaction of recombination catalysed by purified recA protein on naked DNA *in vitro* clearly does not utilise this activity[8-11]. Despite this, it is possible that the protease activity affects the rate of *recA* function *in vivo*. Cellular DNA is complexed with a variety of proteins, so that another role of the protease activity could be to remove such proteins to facilitate the exploration of duplex DNA that must precede strand pairing. An analysis of mutations that affect different activities of recA protein might indicate if this is true.

We thank C. W. Roberts and E. M. Phizicky for advice, discussion and materials; J. Calvo, V. Vogt and B.-K. Tye for criticism of the manuscript; and R. Cunningham, T. Shibata, C. DasGupta and C. Radding for sending us their manuscript prior to publication. This work was supported by NIH grant GM21941 and by a Career Development Award to J.W.R. from the NIH.

Morphogenetic genes *C* and *Nu3* overlap in bacteriophage λ

Jocelyn E. Shaw & Helios Murialdo

Department of Medical Genetics, University of Toronto, Toronto, Canada M5S 1A8

In bacteriophage λ, *genes* C *and* Nu3, *two of the four cistrons which are essential for normal prohead formation, have overlapping nucleotide sequences. These genes are translated in the same reading frame so that the Nu3 protein is identical to the COOH-terminal one-third of the C protein. This structural relationship may provide for the functional interaction of the C and Nu3 proteins through their regions of structural homology during prohead assembly. The in-phase overlapping organisation of genes may constitute a general strategy to facilitate the mutual interaction of a pair of proteins through their common structural domains.*

MORPHOGENESIS of the head of bacteriophage λ is controlled by ten genes clustered in the left arm of the phage chromosome (Fig. 1*a*)[1-7]. Of these genes only *B*, *C*, *Nu3* and *E*, encoding proteins of molecular weights (MWs) 60,000, 58,000, 19,000 and 38,000, respectively, are essential for the production of the head precursor known as the prohead[8-15]. pNu3 acts as the scaffolding protein in prohead construction, directing the assembly of the major capsid protein, pE (refs 14–17). Nu3 protein is subsequently degraded and lost from the prohead structure[14,15,17]. pC is thought to be involved in the early stages of prohead assembly. It is ultimately fused to a minor fraction of the pE molecules in the prohead and cleaved to generate X1 and X2, two polypeptides differing only in the size of their pC-derived moiety. These two proteins, as well as pB and its cleavage product pB*, are the minor components of the mature prohead[14-19].

There is only one available amber mutation in gene *Nu3*—ama8 (ref. 4). Previous examination of the proteins synthesised after infection of non-permissive *Escherichia coli* by $\lambda Nu3_{ama8}$ suggested an unusual relationship between pNu3 and pC (ref. 17). In these studies the mutation in gene *Nu3* resulted not only in the disappearance of pNu3 and the appearance of a Nu3 amber polypeptide, but also in the appearance of a lower MW form of pC. As C protein is known to be susceptible to cleavage[17,18], the production of this altered form of pC was initially attributed to a rapid aberrant cleavage of pC in the absence of functional pNu3 (ref. 17). However, it was noted that the difference in MW between pNu3 and its amber peptide was very similar to the difference in MW between pC and the lower MW form of pC. An alternative explanation for these observations—that the gene products of *C* and *Nu3* have a common COOH terminus—was therefore considered. By this model the

0028-0836/80/010030—06$01.00

two proteins are translated in the same reading frame and terminated at the same site. Thus, the amber mutation in gene *Nu3* is also an amber mutation in gene *C* causing premature termination in the translation of both proteins so that the pC and pNu3 amber polypeptides synthesised by $\lambda Nu3_{ama8}$-infected cells differ in size from the respective wild-type polypeptides by the same amount. This model predicts that mutations within the promoter-proximal region of the *C* gene will affect only the C polypeptide, whereas mutations within the overlapping promoter-distal region will affect both pC and pNu3. Further, the Nu3 protein will be identical to the COOH-terminal region of the C protein, and tryptic peptides of pNu3 (except perhaps the NH_2-terminal peptide) should be a subset of those derived from pC. In this article we describe experiments the result of which support the predictions of such a model.

Fig. 1 Genetic map of λ and expanded map of the *C–Nu3* region. *a*, The vegetative map of λ (not to scale) showing the relative positions of the morphogenetic genes involved in head formation, *Nu1–F*$_{II}$, and tail assembly, *Z–J*. *b*, An expanded map of the *C–Nu3* region drawn to scale. Positions of the *C* and *Nu3* genes and of amber sites are determined from the apparent MWs of the corresponding polypeptides and amber fragments as shown in Fig. 2*a*. The relative positions of the mutations are the same as determined genetically. The λC_{am20} and λC_{am42} mutants, whose amber polypeptides were not observed, have been mapped genetically[47], and their amber sites lie to the left of C_{am39}. The direction of transcription and translation is as indicated.

A missense mutation in gene *Nu3* does not alter the MW of the product of gene *C*

As a preliminary step in the investigation of the relationship between pC and pNu3, we compared the MWs of pC and pNu3 synthesised after infection of *E. coli* with either a λ*Nu3* amber mutant or a λ*Nu3* missense mutant. As originally observed by Ray and Murialdo[17], infection of non-permissive cells with $\lambda Nu3_{ama8}$ results in the synthesis of two altered proteins, as seen in SDS-polyacrylamide gels: (1) pNu3 with a MW of 19,000 (ref. 17) is replaced by its amber fragment $pNu3_{a8}$ of approximate MW 15,000, and (2) pC with a MW of 58,000 (ref. 20) is replaced by pC_{a8}(pC* of Ray and Murialdo), with an apparent MW of about 54,000 (Fig. 2*a*). If the production of pC_{a8} by $\lambda Nu3_{ama8}$ were the result of rapid cleavage of a wild-type C protein in the absence of functional pNu3, as previously suggested[17], the C protein made after infection of cells with a different mutant in gene *Nu3* might suffer similar cleavage and be present as a fragment with the same MW as pC_{a8}. This is not the case. $\lambda Nu3_{t78}$, an absolute defective mutant in gene *Nu3* (ref. 5), directs the synthesis of a pC with a MW of 58,000 the same mobility as that produced in cells infected with λcI_{tl} (wild-type λ) (Fig. 2*a*, *d*). Thus, a nonsense mutation, but not a missense mutation in gene *Nu3*, can alter the size of pC. This result favours the model in which *C* and *Nu3* are overlapping genes.

A gene *C* mutant is also a gene *Nu3* mutant

To test the prediction that mutants in the promoter-distal one-third of the *C* cistron will also be mutant in the *Nu3* cistron, we examined the proteins synthesised in non-permissive *E. coli* infected with a series of amber mutants in gene *C* (Fig. 2*a*). For some of these infections, the C amber polypeptide can be resolved by SDS-polyacrylamide gel electrophoresis (SDS-PAGE), as indicated in Fig. 2, and its size can be used to estimate the position of the corresponding amber mutation within the *C* gene. Assuming that genes *C* and *Nu3* terminate at the same site, a map of the *C-Nu3* region of the λ chromosome can be constructed from the MWs of pC and pNu3, and from the MWs of the amber fragments observed (Fig. 1*b*). When this is done, five of the six *C* mutants tested fall into order within the amino-terminal region exclusive to *C*, whereas C_{am818} falls into the region shared by *C* and *Nu3*. As expected, the mutants located in the non-overlapping portion of the *C* gene fail to produce C protein but make normal amounts of Nu3 protein, whereas λC_{am818} makes neither pC nor pNu3. This scheme agrees with genetic data which show that λC_{am818} is the only *C* mutant of this set that fails to complement $\lambda Nu3_{ama8}$ (data not shown).

The electrophoretic mobilities of both pC and pNu3 are altered by insertion of tyrosine at position am818

The above data are consistent with the overlapping genes model but do not exclude the possibility of double mutations in the strains that affect both pC and pNu3, or polarity of the C_{am818} mutation on gene *Nu3*. To confirm that the observed effects are the result of single mutations, spontaneous revertants of $\lambda cI_{857}Nu3_{ama8}$ and $\lambda cI_{tl}C_{am818}$ were selected on strain 594, a non-suppressing host. Revertants were obtained at frequencies typical for single mutations (10^{-7}–2×10^{-7}) and two revertants of each parent were selected for further study. The polypeptides synthesised in non-suppressing hosts infected with these revertants are shown in Fig. 2*b* and *d*. The two revertants of $\lambda cI_{857}Nu3_{ama8}$ and one revertant of $\lambda cI_{tl}C_{am818}$ (rev 1) produce pNu3 and pC of wild-type MW, indicating that the observed alterations of pNu3 and pC, in both $\lambda cI_{857}Nu3_{ama8}$ and $\lambda cI_{tl}C_{am818}$, are due to single mutations in these phages. The other revertant of $\lambda cI_{tl}C_{am818}$, $\lambda cI_{tl}C_{am818rev2}$, directs the synthesis of C and Nu3 proteins each having an apparent MW about 1,000 less than that of wild-type pC and pNu3. This result is another example of a simultaneous and identical alteration in the mobilities of these two proteins due to a single mutational event. Surprisingly, this mobility change of pC and pNu3 in $\lambda cI_{tl}C_{am818rev2}$-infected cells may be due to the particular amino acid that is now inserted at the former amber site. The following experiment was therefore carried out to see if such a change in mobility could arise from the substitution of a single amino acid. Cells carrying different amber suppressors were infected with $\lambda cI_{tl}C_{am818}$ and the mobilities of pC and pNu3 were examined. Infection of *supD* (Ser-inserting suppressor) and *supE* (Gln-inserting suppressor) cells results in the synthesis of small amounts of pC and pNu3 of wild-type size (and also the amber fragment of *C*, Fig. 2*c*). *supF*-infected cells (Tyr-inserting), on the other hand, synthesise C and Nu3 polypeptides having the same mobilities as those found in $\lambda cI_{tl}C_{am818rev2}$-infected cells, that is, polypeptides with an apparent reduction in MW of 1,000. We conclude that it is the insertion of tyrosine at the C_{am818} site that is responsible for the altered mobilities of these polypeptides. The MWs of the C and Nu3 proteins remain unchanged in infections of all three suppressor strains with $\lambda cI_{tl}C_{am818rev2}$. It seems likely that in $\lambda C_{am818rev2}$ the amber codon has been changed to code for Tyr.

The *Nu3*$_{t78}$ mutation alters the isoelectric points of both pC and pNu3

To probe further the model that the C and Nu3 proteins share a common coding region, we investigated the properties of these two proteins synthesised by $\lambda Nu3_{t78}$-infected cells. $\lambda Nu3_{t78}$, as

Fig. 2 Polypeptides synthesised after infection of host cells with mutants in genes *C* and *Nu3*. *a*, Strain 159 (ref. 48) (tracks 1–7) or 159 ($\lambda imm^{434}ind^{-}$)[20,49] (tracks 8–10) was UV irradiated with an incident dose of 500 J m^{-2}, infected at a multiplicity of infection (MOI) of 5 with the indicated phage and labelled at 20–30 min after infection[17] with 75 μCi of ^{35}S-hydrolysate[50] per ml of culture. Radiolabelled polypeptides were separated by SDS-PAGE on a 14–20% gradient gel and visualised by autoradiography. *b*, Strain 159 was UV irradiated, infected with the indicated amber mutants and revertants at an MOI of 5. Proteins were labelled and analysed as in *a*. *c*, Strain 159 (*sup*^{0}), WC5041 (*supE*), WC5043 (ref. 4) (*supD*) or 159*supF* (ref. 51) (*supF*) was UV irradiated, infected at an MOI of 5 with $\lambda cI_{t1}C_{am818}$ or $\lambda cI_{t1}C_{am818rev2}$ as indicated. Proteins were labelled and analysed as in *a*. *d*, Strain 159 was UV irradiated, infected with the indicated phage at an MOI of 5. Proteins were labelled as in *a* and separated by SDS-PAGE on a 12.5% gel. For SDS-PAGE, extracts were boiled in SDS-gel electrophoresis sample buffer for 1 min and the radiolabelled polypeptides electrophoresed using the discontinuous buffer system of Laemmli and Maizel[52] with the slab gel apparatus described by Studier[53] modified to accommodate 20-cm separating gels. The acrylamide concentration in the separating gels was either 12.5% or a linear gradient of 14–20%. Although separating gels containing 12.5% acrylamide allow better resolution of pC, 14–20% gradient gels are, in general, required for resolution of pNu3.

mentioned above, is an absolute defective mutant in gene *Nu3* that produces C and Nu3 proteins of wild-type MW. Extracts of cells infected with this mutant were analysed by two-dimensional isoelectric focusing and SDS-PAGE[21]. Comparison of the two-dimensional pattern of polypeptides from λcI_{tl}- and $\lambda Nu3_{t78}$-infected hosts reveals that both $pNu3_{t78}$ and pC_{t78} are more basic than the respective wild-type proteins (Fig. 3). This is most clearly seen when samples from extracts of λcI_{tl}- and $\lambda Nu3_{t78}$-infected cells are mixed and run together in the same gel (Fig. 3*c*). All other proteins synthesised in the mutant infection have the same mobilities as in a wild-type infection, with the exception of three minor proteins of slightly lower MW than pC which are polypeptides derived from C protein (pC-associated minor bands of Ray and Murialdo)[17].

The tryptic peptides of pNu3 are a subset of the tryptic peptides of pC

^{35}S-labelled proteins C and Nu3 and polypeptides pC_{a8} and $pNu3_{a8}$ were isolated by SDS-PAGE, eluted from the gel, digested with trypsin and the resulting peptides separated by electrophoresis and chromatography on cellulose thin layer plates[22]. The radiolabelled tryptic peptides of pNu3 are all contained within the peptide map of pC (Fig. 4), indicating that these two proteins have common amino acid sequences. In addition, the tryptic peptide missing (peptide 1) from the fingerprint of the amber polypeptide $pNu3_{a8}$ is also absent in the peptide map of pC_{a8}. This indicates that the $Nu3_{am8}$ mutation results in the production of amber polypeptides of C and Nu3 both lacking the same COOH-terminal amino acid sequence, and demonstrates that the Nu3 protein and the COOH-terminal portion of the C protein are encoded by the same DNA.

Conclusions and implications

The results presented here demonstrate that the Nu3 protein and the COOH-terminal one-third of the C protein are encoded on the same DNA. The Nu3 protein is not derived from pC by proteolytic processing because all the *C* amber mutants located in the NH_2-terminal (non-overlapping) portion of the gene direct the synthesis of normal amounts of Nu3 protein. It is possible that C protein is not a primary gene product but arises from the fusion of Nu3 protein with a polypeptide encoded in the region immediately preceding gene *Nu3*. However, this seems unlikely as co-infection of cells with *C* amber and *Nu3* amber mutants does not result in the production of pC with wild-type MW. Furthermore, pulse–chase experiments fail to provide any evidence of a short-lived precursor to pC (data not shown). We therefore believe that the *Nu3* gene lies within the *C* gene. Translation of the two proteins is in the same reading frame and termination of translation occurs at or near the same site.

It is not known whether translation of the Nu3 protein is initiated internally to C on a common mRNA or whether the two proteins are translated separately from two different mRNAs. In two other instances of overlapping genes in which this has been investigated—the polyoma proteins VP2 and VP3 (refs 23, 24), and A and A* proteins of ΦX174 (ref. 25)—all the proteins seem to be translated from distinct species of mRNA. In the case of the C and Nu3 proteins of λ, there is no evidence to exclude the possibility of translation from either a common mRNA or separate RNAs. Although there is probably not a separate promoter for the transcription of the *Nu3* gene[26], it is possible that the primary polycistronic late transcript initiated from P'_R (ref. 27) is modified so that pC and pNu3 are translated from different species of mRNA. On the other hand, the functional halflife of the *C* mRNA is about half that of the *Nu3* mRNA[28], which is compatible with their being translated from the same transcript. Also, about two- to threefold more copies of pNu3 than pC are synthesised in an infected cell (data not shown), suggesting that there is a relatively strong ribosome binding site for *Nu3* within the *C* gene. This might allow internal initiation for the translation of pNu3 on a common transcript. In any event, we have observed that translation of the C protein probably interferes with translation of pNu3. In cells infected with λC_{am737}, the most promoter-proximal amber mutation in the *C* gene, the amount of Nu3 protein synthesised is about 1.5–2 times as much as is produced in a wild-type infection (data not shown). Although probably not important in the case of the C and Nu3 proteins of λ, interference in the synthesis of the promoter-distal protein by the translation of the promoter-proximal polypeptide could be a means of regulating the level of the downstream protein in an overlapping gene pair[29–32].

There are several examples of overlapping genes in the small double-stranded bacteriophages ΦX174 (refs 32–35) and G4 (refs 36, 37) in the RNA phage *Qβ* (refs 38–40) and in the

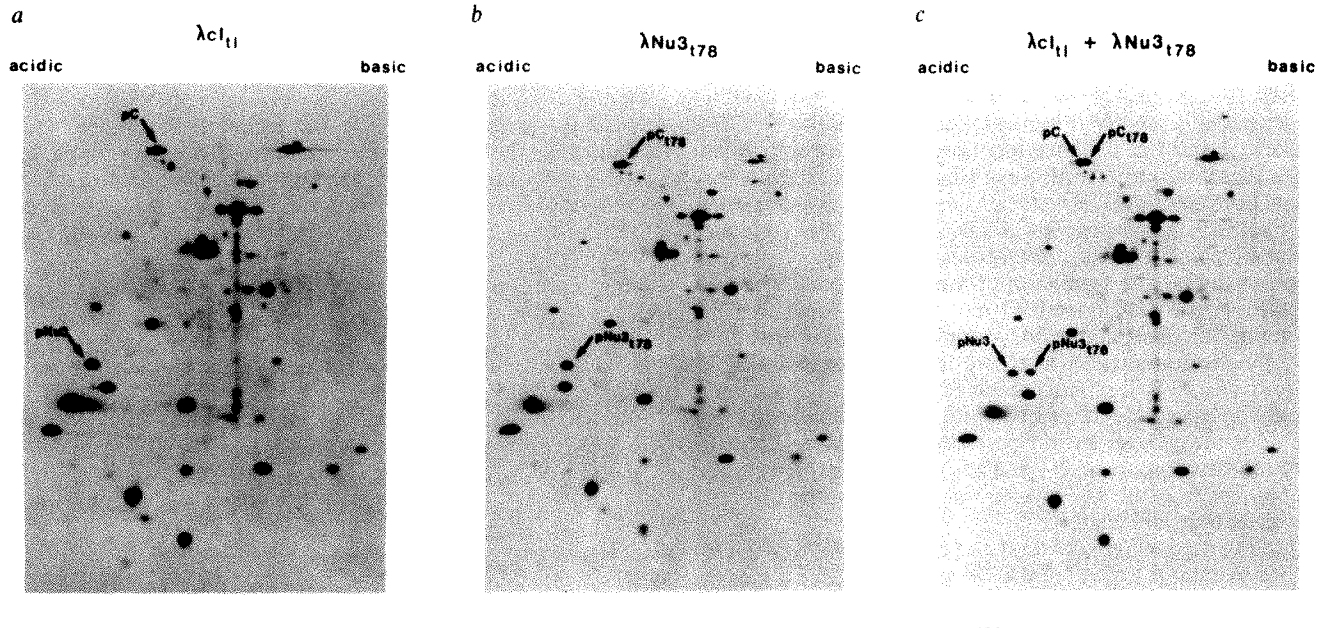

Fig. 3 Two-dimensional separation of proteins synthesised in $\lambda Nu3_{t78}$- infected cells. Strain 159 ($\lambda imm^{434} ind^-$) was UV irradiated, infected with either λcI_{tl} or $\lambda Nu3_{t78}$ at an MOI of 5, and labelled with ^{35}S-hydrolysate at 20–30 min after infection. The proteins were separated in the first dimension by isoelectric focussing in gels containing 2% ampholytes (*w*/*v*) (20% *p*H 3.5–10, 80% *p*H 5–8) and in the second dimension by SDS-PAGE on a 14–20% gradient gel[21]. Radiolabelled polypeptides were visualised by fluorography[54]. *a*, λcI_{tl}; *b*, $\lambda Nu3_{t78}$; *c*, 1:1 (v/v) mixture of samples in *a* and *b*.

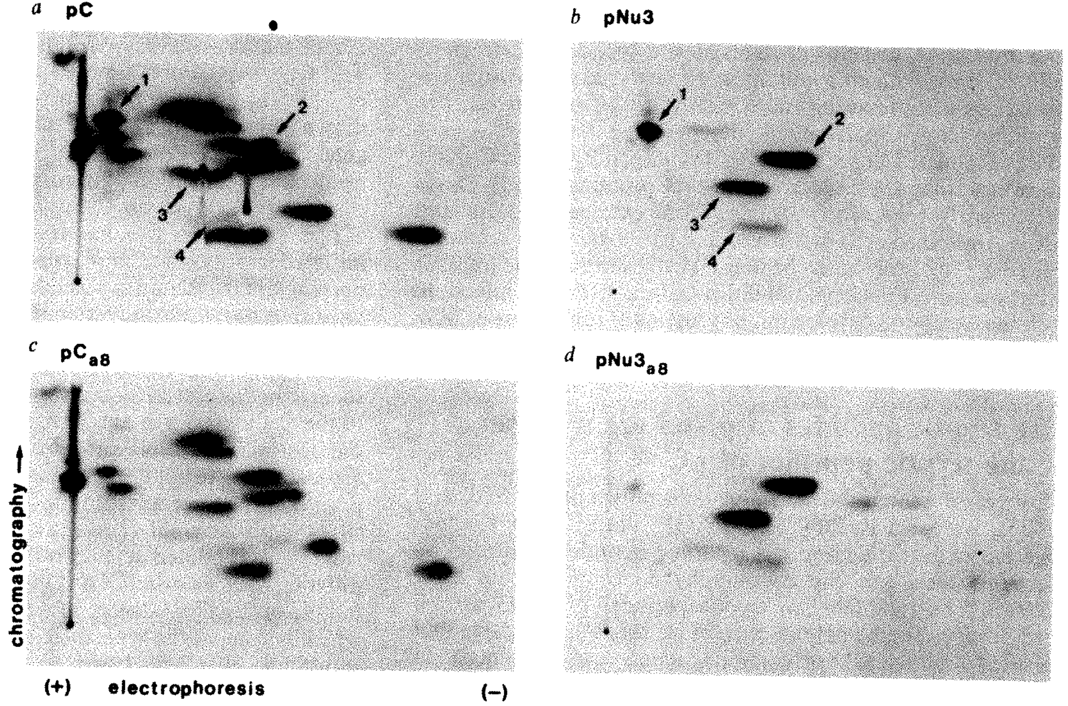

Fig. 4 Tryptic fingerprints of pC, pNu3, pC$_{a8}$ and pNu3$_{a8}$. Strain 159 was UV irradiated and infected with either $\lambda cI_{26}b221E_{am815}$ for preparation of pC and pNu3 or $\lambda cI_{857}Nu3_{ama8}FI_{am785}$ for preparation of pC$_{a8}$ and pNu3$_{a8}$. Use of these particular phage strains allows isolation of pNu3 and pNu3$_{a8}$ relatively free of contaminating labelled phage proteins. The infected cells were labelled at 20–30 min after infection with ^{35}S-hydrolysate and proteins were separated by SDS-PAGE on a 12.5% gel. Radiolabelled polypeptides were visualised by autoradiography and pC, pNu3, pC$_{a8}$ and pNu3$_{a8}$ were cut out of the gel, eluted, oxidised with performic acid, and digested with trypsin[22]. Analysis of the isolated but undigested proteins by SDS-PAGE on a 14–20% gradient gel indicated that pC, pNu3 and pC$_{a8}$ were free of contaminating labelled proteins. pNu3$_{a8}$ contained minor amounts of contaminating material. The tryptic peptides were separated by electrophoresis and chromatography on cellulose thin layer plates[22]. Peptides from pC(*a*) and pNu3 (*b*) were run simultaneously, in parallel, on one thin layer plate, as were peptides from pC$_{a8}$ (*c*) and pNu3$_{a8}$ (*d*). Peptides derived from pC and pNu3 having identical mobilities are indicated by arrows.

papovaviruses polyoma[41] and SV40 (refs 42, 43). It has been argued that the overlapping organisation of genes in these viruses offers the advantage of efficient use of a limited coding capacity. From this viewpoint, the discovery of an overlapping pair of genes in λ may be somewhat surprising, as λ has a relatively large genome with a large non-essential region which itself may contain an overlapping gene pair (C. Epp and M. Pearson, personal communication). This may indicate that an overlapping genetic arrangement is a fairly widespread phenomenon with additional advantages to the organism. The fact that pC and pNu3 are translated in the same reading frame suggests that the role of the overlap, in this instance, is to generate a pair of proteins with a specific structural relationship essential for proper prohead assembly. The overlapping arrangement of *C* and *Nu3* ensures that pNu3 and the COOH-terminal one-third of pC have identical amino acid sequences and are therefore structurally very similar, whereas the NH$_2$-terminal portion of pC is structurally unique. A possible model for λ prohead morphogenesis is one in which the common domains of pNu3 and the COOH-terminal region of pC copolymerise during the formation of a prohead core structure. Molecules of pC thus assembled into the core could further interact through their unique NH$_2$-terminal domains with other morphopoietic proteins such as pE, during the polymerisation of the capsid. (An NH$_2$-terminal portion of pC is known to interact with pE, the major capsid protein, and by fusion with pE and cleavage of the pC–pE hybrid polypeptide produces the two minor prohead components X1 and X2 (ref. 15).) In this way, pC might be viewed as a linker between two different substructures, the prohead core and coat.

Of the overlapping genes translated in phase that have been described to date (*A* and *A** of ΦX174 and G4, *VP2* and *VP3* of the papovaviruses, and A_1 and *coat* of *Qβ*), the VP2 and VP3 proteins of polyoma and SV40, and the A_1 and coat proteins of *Qβ* (ref. 44) are essential for viral morphogenesis. The VP2 and VP3 proteins, organised genetically in an analogous fashion to pC and pNu3 of λ, have common COOH-terminal regions whereas the coat protein and A_1 protein, a readthrough product of the *coat* gene, have identical NH$_2$-terminal sequences. In polyoma, recent experiments suggest that VP2 and VP3 form the pentons of the capsid[45]. This is consistent with the model that these proteins interact with one another because of their common amino acid sequence. Thus, the in-phase overlapping arrangement of genes could be a general strategy to generate a pair of proteins, such as pC and pNu3, with regions of structural homology and non-homology. The structural relationship between the proteins of such a pair may result in their mutual interaction through the shared structural domain[46] while allowing individual specialised reactions through their unique structural domains. In this way, interactions involving each protein of the pair could be physically coupled to facilitate the assembly of a complex biological structure.

We thank Wendy L. Fife for technical assistance, Mark Pearson in whose laboratory much of this work was done, and Andrew Becker and Mark Pearson for critical reading of this manuscript. This research was supported by grants from the MRC of Canada (MT-3325) and the NIH (GM24361-02).

The complete variable region sequences from ten antibodies and two myeloma proteins binding α-1,3 dextran have been determined. The diversity patterns of these homogeneous antibody molecules suggest that the variable regions of heavy chains are encoded by separate variable (V) and joining (J) gene segments. The most striking feature of these data is the extensive sequence variability of a region that we denote the D (diversity) segment which is located at the junction between the V and J segments in the centre of the third hypervariable region. The D segment diversity may arise from a novel somatic mutational mechanism or may be encoded by multiple D gene segments. For the first time, the amino acid sequence correlates of several V region idiotypes are determined.

STUDIES of immunoglobins at the protein and DNA levels have led to striking advances in our understanding of the organisation and evolution of antibody genes and mechanisms of antibody diversity[1–4]. There are three unlinked families or clusters of antibody genes—the λ and κ gene families encode light (L) chains and the heavy (H) gene family encodes heavy chains[5]. The κ or λ gene is composed of four distinct gene segments, leader (L), variable (V), joining (J) and constant (C), which are separated by intervening sequences in undifferentiated or germ-line DNA[6–12]. Heavy chain genes probably have a similar organisation of gene segments (P. Early, H. Huang, M. Davis and L.H., unpublished observations). During the differentiation of antibody-producing cells, the V_L and J_L gene segments are juxtaposed and together encode the variable or antigen-binding domain of the antibody molecule. (The term V or J segment will refer to the corresponding protein sequence; the term V or J gene segment will refer to the corresponding DNA coding regions.) Comparative amino acid sequence analyses of V regions showed that for both light and heavy chains, there are three regions of extreme variability termed hypervariable regions[13,14], which fold in three dimensions to constitute the walls of the antigen-binding site[15,16]. The diversity in the hypervariable regions of L chains has been most extensively studied and explained by a variety of genetic mechanisms. (1) There are many germ-line V_κ (and J_κ) gene segments[5,10]. (2) A single V_κ gene segment may be joined to many different J_κ gene segments and conversely, a single J_κ gene segment may be joined to many different V_κ gene segments[17]. As the boundary of the V_L and J_L segments falls within the third hypervariable region, the combinatorial joining of these segments contributes to the diversity of antigen-binding sites. (3) Random single base mutations may occur throughout the V_L (and J_L) gene segments and those variants exhibiting altered and useful antigen-binding properties may be selected for clonal expansion. For example, 12 of 18 V_λ regions examined were identical to one another[18–20]. The six variant V_λ sequences differed from the 12 identical sequences by between one and three amino acid substitutions. All these substitutions occur in the hypervariable regions. These data suggest that a single V_λ gene is often expressed unchanged and less frequently is modified by somatic mutation to produce the variants. Recent DNA sequence analyses of germ-line and myeloma λ gene segments are consistent with this supposition[6,11,12]. The pattern of diversity wherein variant V region sequences exhibit few substitutions mostly concentrated in the hypervariable regions will be denoted λ-type diversity. (4) A site-specific recombinational mechanism has been postulated to explain amino acid sequence diversity at the junction of V_κ and J_κ gene segments[21–23]. This diversity is reflected as single codon substitutions at the N-terminal residue of the J_κ segment and as the insertion or deletion of single codons precisely at the V-J junction[23]. This pattern of diversity will be denoted the V-J junctional diversity.

We have analysed the diversity patterns in mouse antibodies directed against a simple antigenic-determinant, α-1,3 dextran, in order to determine the relative contributions of the diversification mechanisms discussed above. The hybridoma technique of Köhler and Milstein facilitates the analyses of antibody diversity by making large quantities of antigen-induced, homogeneous antibody molecules available[24]. This is accomplished by fusing normal antibody-secreting cells with mouse plasmacytoma cells[25]. The hybrid cells generate immortal cell lines that secrete large amounts of homogeneous antibody molecules of the two parental cell types. The light chains of the dextran antibodies are all of the λ type and appear to be very similar, if not identical, to one another. Hence, most of the diversity in the dextran system appears to reside in the

heavy chains. We report here the complete amino acid sequences from the variable regions of 10 heavy chains derived from hybridoma antibodies to dextran. These data suggest that heavy chains have a D (diversity) segment located in the heart of the third hypervariable region. The D segment may be encoded by a separate germ-line gene segment or generated by a new type of somatic mutational mechanism.

Immunoglobulins binding dextran

Immunoglobulins binding dextran exhibit limited heterogeneity in several respects. First, preliminary amino acid sequence studies on two myeloma proteins binding α-1,3 dextran, M104E and J558, revealed that the V_L regions are identical[18,19] and that the V_H regions are identical through their first hypervariable regions[26]. The N-terminal sequences of V_H regions derived from normally-induced pooled serum antibodies to α-1,3 dextran also are identical to their myeloma counterparts[27]. Second, isoelectric focusing analyses of anti-dextran antibodies of the IgG class demonstrate limited heterogeneity with considerable sharing of bands between sera from different mice[28]. Moreover, the serum antibody light chains are identical to one another and to their myeloma counterparts by isoelectric focusing criteria[27]. Third, the light chains from the 10 hybridomas and 2 myeloma proteins reported here are all of the λ type and have identical isoelectric focusing patterns (J.S., unpublished observation). Thus, light chains from dextran antibodies appear to be very similar, if not identical, to one another. Therefore, most of the diversity in the antibodies to α-1,3 dextran must reside in the heavy chains. Fourth, the anti-α-1,3 dextran antibodies can be divided into several general categories by idiotypic analyses[29]. More than half of the anti-α-1,3 dextran antibodies from mice immunised with the branched dextran B1355 share a variable-region antigenic determinant or idiotype with both the M104E and J558 proteins. This idiotype is absent from non-dextran binding immunoglobulins and λ light chains and is denoted the 'cross-reactive' or IdX idiotype. Antibodies with the IdX idiotype are synthesised by multiple different antibody-producing clones. Additional idiotypes specific for either the M104E or the J558 immunoglobulins are present on a minor fraction of the normally-induced antibodies. These idiotypes are denoted as individual or IdI idiotypes (for example, IdIM104E and IdIJ558). Another general category of dextran antibodies is that of those lacking the IdX determinant (IdX negative). The IdX-positive and IdX-negative antibodies to dextran are structurally very similar in that their light chains are identical by isoelectric focusing analysis and the heavy chains from both the IdX-positive and IdX-negative pools of serum antibodies are identical to the heavy chains of the M104E and J558 immunoglobulins for their N-terminal 27 and 53 residues, respectively[27]. These observations show that much of the V domain diversity in normal antibodies to α-1,3 dextran resides in the heavy chain beyond residue 53. Thus, we turned to the amino acid sequence analysis of homogeneous normal antibodies to α-1,3 dextran.

Diversity patterns in V_H regions from antibodies binding dextran

Figure 1 gives the complete amino acid sequences of V_H regions from 2 myeloma proteins and 10 hybridoma antibodies that bind dextran. The hypervariable regions and the variable region site of carbohydrate attachment are indicated. These V_H regions are compared to the published sequence of the myeloma M104E V_H region[30] with amino acid substitutions indicated by the one-letter code[31].

Two features are of interest in this set of V_H regions. First, each of these 12 V_H regions differs from all of the others by 1 to 13 amino acid substitutions (Fig. 1). We have not yet detected a pair of identical V_H regions in 12 attempts. Accordingly, the V_H sequence diversity in the antibody response to α-1,3 dextran is extensive. Second, patterns of variability divide the V_H regions from dextran antibodies into three distinct sections—V(1–99), V(100–101) and V(102–117). The highly variable section, V(100–101), separates the other two sections which are relatively conserved. Section V(100–101) exhibits nine different sequences in the 12 V_H regions (Fig. 2). Indeed, position 100 has eight alternatives and position 101 has four. In contrast, nine V_H regions have identical sequences for section V(1–99) and the remaining V_H regions differ by between two and seven residues from the others. Likewise, nine V_H regions have identical sequences for the section V(102–117), two have a second sequence (Hdex4 and Hdex5) and one has a third sequence (Hdex1). Thus, the relatively conserved sections V(1–99) and V(102–117) are separated by two highly variable residues at positions 100 and 101.

This same three-section pattern is seen when 20 completely sequenced V_H regions are aligned by homology with their anti-dextran counterparts (Fig. 3). The section homologous to V(1–99) can clearly be defined in each of these 20 V_H regions and each terminates precisely at the position homologous to 99 in the heavy chains binding dextran (Fig. 3). The homology relationships among the V(102–117) sections are also obvious. The V(102–117) sections from the various V_H regions are identical in size, apart from the levan-binding immunoglobulins, and exhibit extensive amino acid sequence homology to one another (56–100% sequence identity). Accordingly, sections homologous to V(1–99) and V(102–117) in the dextran V_H regions are clearly present in all of the other V_H regions examined to date. In contrast, there is no homology in the V(100–101) regions between these two sections because of extensive sequence and size variability (Fig. 3). The sections analogous to V(100–101) can be defined only as those residues remaining after the V(1–99) and V(102–117) sections have been assigned for each V region by homology.

Implications of V_H diversity patterns for gene organisation

The patterns of amino acid diversity in the V_H regions from antibodies binding α-1,3 dextran allow us to define tentatively V_H and J_H segments with properties similar to their light chain counterparts (Figs 1–3). The V(1–99) section appears to correspond to the V_H segment and V(102–117) section appears to

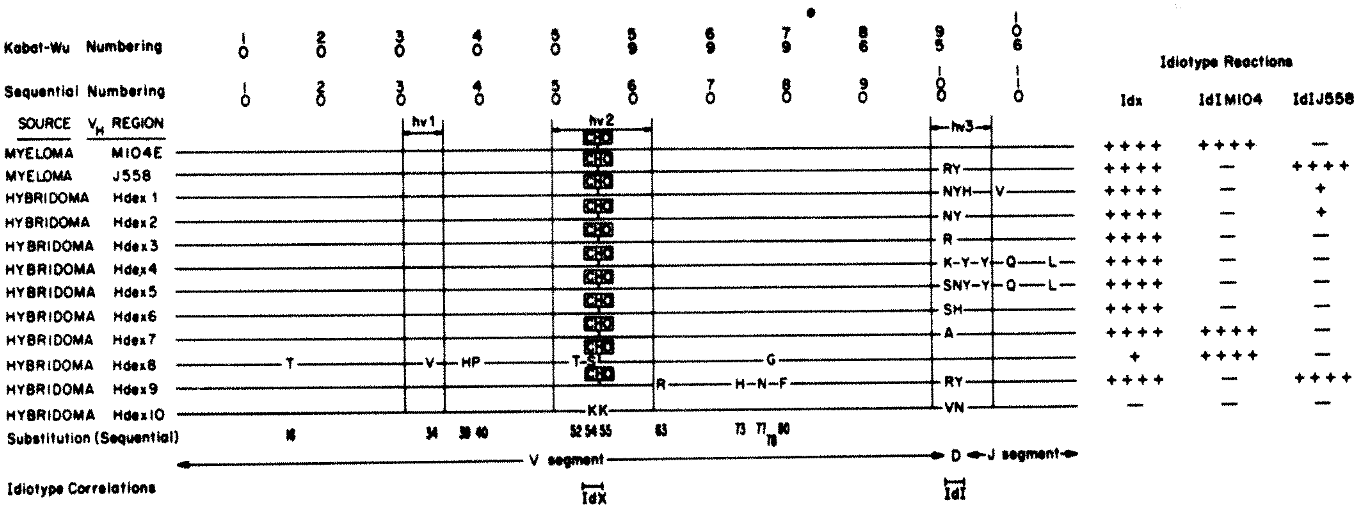

Fig. 1 The amino acid sequences and idiotypes from V regions of myeloma proteins and homogeneous hybridoma antibodies binding dextran. The myeloma protein M104E is used as a prototype sequence and variation from this sequence is indicated. The hypervariable regions are indicated by hv1, hv2 and hv3, respectively. CHO indicates the attachment of a carbohydrate moiety. The one-letter amino acid code of Dayhoff is used[31]. The V and J segments are indicated by arrows. The D segment includes positions 100 and 101. Sequential numbering denotes consecutive numbering of the V_H regions. The Kabat–Wu numbering is from ref. 36. Details of the complete heavy chain sequence of the M104E immunoglobulin are published elsewhere[30]. A similar strategy was used for the sequence analysis of the V_H regions from the hybridomas. The positions of amino acid substitutions in V segments are indicated. Eight hybrids were derived from individual BALB/c mice: Hdex6, 7, 8 and 9 were obtained at 5 or 6 days after a single injection of 100 μg dextran B1355 in complete Freund's adjuvant (CFA), and Hdex2, 3, 4 and 10 were obtained 1–3 days after hyperimmunisation with dextran in CFA followed 1–2 months later with 3 interperitoneal injections of 2×10^9 *Escherichia coli* at 2-day intervals. Hybrids Hdex1 and 5 were derived from a single (BAB-14 × BRVR)F_1 mouse at 7 days after the dextran–*E. coli* protocol. Hybrids were generated as described by Galfre *et al.*[41] using the HGPRT-deficient MPC-11 ($\gamma_{2b}\kappa$) line, 45.6TG1.7, (Hdex1, 3, 4, 5 and 10) or a non-secreting variety of the MOPC-21 ($\gamma_1\kappa$) line, NSI/1-Ag4-1, which synthesises but does not secrete κ chains (Hdex2, 6, 7, 8 and 9). Anti-dextran secreting hybrids were detected by direct binding of ^{125}I-dextran by culture supernates either in a tube-binding assay or after isoelectric focusing in polyacrylamide gels. Hybrids were cloned in soft agar[42] over feeder layers and grown in BALB/c mice as ascites tumours. The antibodies produced by the hybrids appeared representative of those found in the serum at the time of fusion. Idiotypes were determined as described by ref. 29. ++++ Indicates a reaction 10 times as strong as +; – indicates no reaction.

represent the J_H segment. The V(100–101) section will be called the D (diversity) segment and its origin will be discussed.

The extensive variability in these V_H regions at position 100 appears to mark the C-terminal end of the V_H segment, just as extensive variability at position 96 marks the C-terminal end of the V segment in kappa light chains[17]. The correspondence of V(1–99) to a V_H gene segment is confirmed by the DNA sequence analysis of a germ-line V_H gene segment which ends precisely at codon 99 (P. Early, H. Huang, M. Davis and L.H., unpublished observation).

The J_H segment includes at least positions 102–117. The C-terminal boundary of the J_H segment at position 117 has been defined by the DNA sequence analysis of an expressed V_H-J_H gene (H. Huang, P. Early, M. Davis and L.H., unpublished observations). This analysis demonstrates that the C_H region begins at a position homologous to residue 118 in the heavy chains from antibodies binding dextran, in agreement with the J_H and $C_{\gamma1}$ gene segment boundaries defined by DNA sequence analysis of a $C_{\gamma1}$ gene[32]. The N-terminal boundary of the J_H segment is unclear. Figure 2 shows three J_H sequences which differ from each other by two or three two-base substitutions (J_1, J_2 and J_3). Position 102 is the first position in the J_H segment at which linkage relationships among amino acid residues appear. A tryptophan at position 102 is invariably linked to valine, alanine and valine residues at positions 106, 109 and 113, respectively, in the J_1 segments, whereas the tyrosine at position 102 is linked to tyrosine, glutamine and leucine at these positions in the J_2 segments (Fig. 2). These linkage relationships imply that the J_1 and J_2 segments are encoded independently in the germ-line. The D segment comprises positions 100 and 101 and may or may not be a part of the J segment, depending on how V–J junctional diversity arises. These assignments of the V_H, J_H and D segment boundaries also are supported by the homology relationships exhibited among the other completely sequenced V_H regions (Fig. 3).

The D and J_H segments comprise almost the entire third hypervariable region (Fig. 2). This is in striking contrast to the J_κ segment which just extends into the third hypervariable region by a single residue[17]. Moreover, the size variation seen in the D segment of heavy chains is far more extensive than that seen at the V–J boundary of kappa chains.

Rudikoff and coworkers have used more limited V_H region data to suggest the V_H segment extends from 1 to 98 and the J_H segment from 105 to 117. They conclude that positions 99 to 104 may be part of the V segment or, alternatively, part of the J segment[33]. These assignments are different from those made here.

Implications of V_H diversity patterns for mechanisms of antibody diversity

The V_H regions from dextran antibodies all differ from one another. Let us analyse possible contributions to this diversity by multiple germ-line gene segments, somatic mutation and the combinational joining of V_H and J_H segments.

Germ-line V_H and J_H gene segments. Four different amino acid sequences corresponding to the V_H gene segment are present in the 12 antibodies binding dextran and these are denoted V_1 to V_4 in Figs 1 and 2. The V_1 segment is expressed in nine different immunoglobulins binding dextran and, accordingly, appears to be encoded by a germ-line gene. This supposition follows from the improbability of generating the same V_H sequence many times by somatic mutation[4]. The V_2, V_3 and V_4 segments differ from V_1 by seven, four and two residue substitutions, respectively. The V_2, V_3 and V_4 segments may be encoded by distinct germ-line V_H gene segments or these sequences may arise from one or more somatic mutational mechanisms. However, the diversity patterns among the V_2, V_3 and V_4 segments do not resemble either of the two somatic mutational patterns described earlier for light chains, λ-type diversity and V_κ-J_κ junctional diversity.

Fig. 2 The C-terminal portions of V_H regions from immunoglobulins binding dextran. See Fig. 1 legend. The number of alternative amino acids for each position at which variability exists are indicated. The number of base substitutions denotes the minimum number of nucleotide changes required to convert the most common codon at a particular position into the alternative codons at that position. The V_1 to V_4 and J_1 to J_3 segments are defined. The third hypervariable region is denoted by hv3. Three pairs of proteins with identical sequences at positions 100 and 101 are set apart from the rest. The V_H, D and J_H segments are defined in Fig. 1.

The three different J_H segments differ from one another by two to five residue alternatives (Fig. 2). Moreover, most of these J_H segment substitutions require two or even three base substitutions and repeats of two of these sequences have been seen. These observations strongly suggest that the three J_H sequences are directly encoded by three germ-line J_H gene segments. The J_H diversity noted in Fig. 3 appears to be significantly greater than the corresponding J_L diversity[17] and, accordingly, may be encoded by a larger number of germ-line J_H gene segments.

Combinational joining. The combinational joining of V_H and J_H gene segments to encode many distinct V_H regions provides yet another source of antibody diversity (Fig. 4). For example, identical J_H segments may be associated with differing V_H segments (such as M104E and Hdex8; J558 and Hdex9). Conversely, identical V_H segments may be associated with different J_H segments (for example, Hdex1, Hdex2 and Hdex4) (Fig. 1). Even more striking is the observation that the J_1 segment in V_H regions from antibodies binding dextran also occurs in the very different V_H regions from myeloma proteins binding phosphorylcholine (Fig. 3). Likewise, the same J_H segment may be found in heavy chains binding phosphorylcholine and galactan (for example, M167 and T601). Thus, the combinational joining of J_H and V_H gene segments appears to be an important source of diversity in these dextran-binding antibodies.

D segment diversity. This most striking diversity pattern in these V_H regions (Figs 2, 3). Diversity in the D segments may arise from one of three general mechanisms: (1) a novel somatic mutation mechanism possibly occurring as a result of the joining of V_H and J_H gene segments; (2) a large number of germ-line J_H or V_H gene segments which include the D segment; or (3) a third gene segment (D) encoding positions 100 and 101 which is joined with the V_H and J_H gene segments during the differentiation of an antibody-producing cell. Let us consider what constraints the diversity patterns of the V_H regions impose on each of these models.

Several observations argue against many germ-line V_H gene segments extending from codons 1 to 101. First, identical D segments may be associated with different V_H segments—M104E-Hdex8 and J558-Hdex9 (Fig. 1). Thus, the D segments appear to associate independently with V_H segments. Second, the T15 V_H gene segment terminates at codon 99 (P. Early, H. Huang and L.H., unpublished observation). Accordingly, the D segment cannot be encoded as part of the V_H gene segment for the T15 V_H gene segment (Fig. 3). Identical D segments may be associated with different J_H segments—Hdex1-Hdex2 and X44-J539 (Fig. 3). A more striking example of this independent association of D and J_H segments is the observation that a J_1 segment is associated with very different D segments in immunoglobulins binding distinct haptens—T15 and M104E (Fig. 3). The independent segregation of D segments with both V_H and J_H segments suggests that the D coding regions are not merely germ-line extensions of V_H or J_H gene segments. In addition, homology comparisons among the V_H regions very clearly define the V_H and J_H segments (Fig. 3). In contrast, the D segments lack constancy both in size (0 to 7 residues) and amino acid sequence (20 different sequences in 25 different V_H regions compared) (Fig. 3). The V_H regions in Fig. 3 would require a very large number of germ-line gene segments if the V_H or J_H gene segments include the D segment.

The D segment diversity is quite distinct from the V–J junctional diversity of kappa chains in several regards. First, there are extensive size differences among the D segments whereas the κ junctional diversity shows at most the insertion or deletion of just a single codon[23]. Second, the two codons for the D segment associated with a particular $V_H(V_1)$ and a particular $J_H(J_1)$ segment exhibit three different nucleotide alternatives at three positions—100a, 100b and 101a (Table 1). This observation is important because it suggests that D segment diversity cannot be generated solely by recombination between the V_1 and J_1 gene segments as is suggested by the site-specific recombinational model of mouse kappa chains[21–23]. This model allows for only two alternatives at any nucleotide position. Accordingly, the extensive variability, the size differences and the presence of three bases at several nucleotide positions in the D segments constitute a distinctly new pattern of diversity that must be explained by a novel mechanism for somatic mutation or the presence of multiple D gene segments.

The striking base invariance at nucleotide positions 101b and

101c in the midst of the remarkable adjacent diversity raises several interesting possiblities (Table 1). Perhaps these invariant nucleotides form part of a recognition site for an enzyme that might mediate somatic mutation or join the D and J_H gene segments together. Alternatively, perhaps these invariant nucleotides are a part of the J_H gene segment.

If the D segment is encoded by a gene segment separate from the V_H and J_H gene segments, then heavy chain genes differ in a major organisational feature from light chain genes. Moreover, the presence of a putative D gene segment creates a second gene segment boundary (V_H–D and D–J_H) at which junctional diversity of the type noted in kappa chains can occur[21-23].

Antigen-binding diversity and V_H variability

The third hypervariable region forms an important part of the antigen-binding site[15,16]. Diversity in the dextran antibodies is concentrated in the third hypervariable region of heavy chains which includes the D segment and much of the J_H segment (Fig. 2). Studies on the binding specificites of the myeloma proteins M104E and J558 which differ only in the D segment have demonstrated that the antigen-binding properties of these two molecules are quite distinct[34,35]. Accordingly, the mechanism for producing D segment diversity does have an important role in modifying the antigen-binding properties of antibodies.

Variability in the third hypervariable region of the dextran antibodies arises from germ-line diversity (J_H segments), by combinational joining of V_H and J_H (and possibly D_H) segments and by the mechanism for producing D segment diversity. Of these, D segment diversity appears to be by far the most extensive and, presumably, important in generating a diversity of antigen-binding sites (Figs 2, 3).

One striking feature evident in Fig. 3 is that immunoglobulins binding particular haptens share similar V_H segments, exhibit D segments of similar size (for example, zero for levans, four for galactans, and so on), and to a lesser extent share similar J_H segments. Whether these correlations arise through some intrinsic properties of gene organisation, somatic mutational mechanisms or antigen selection is unknown.

Correlation of dextran idiotypes and protein structure

Several interesting conclusions can be drawn about the correlation of V_H structure and the various idiotypes of dextran-binding antibodies (Fig. 1). First, the individual idiotype appears to correlate with the D segment sequence. The V_H regions from the M104E and J558 proteins differ only by their D segments. As the light chains are identical, the individual idiotypes of M104E and J558 must be determined by positions 100 and 101. Moreover, the V_H region of Hdex9, which differs from that of J558 by four residues and is identical at positions 100 and 101, has the individual J558 idiotype. Likewise, the V_H region of Hdex8, which differs from that of M104E by seven residues and is identical in the D segment, also has the individual M104E idiotype. However, a single residue substitution can eliminate the individual idiotype as demonstrated by the observation that Hdex3 is lacking both the M104E and J558 individual idiotypes (Figs 1, 2). Partial and in one case complete IdI reactivity can be retained by D segments sharing one of two residues (Hdex1, Hdex2 and Hdex7). The overall conclusion is that the individual idiotypes of myeloma proteins M104E and J558 are determined by residues 100 and 101 and, accordingly, are either encoded by a third gene segment (D) or represent antigenic determinants generated by a novel somatic mutational mechanism. Second, the IdX idiotype correlates with several residues in the V_H segment. The V_H region from one IdX-negative protein, Hdex10, has been sequenced. Hdex10 differs from the two myeloma V_H regions by four residues—positions 54, 55, 100 and 101. The substitution at position 55 destroys the attachment site for the carbohydrate moiety, distinguishing it from the other

Fig. 3 A comparison of published heavy chain sequences including the C-terminal portions of V_H regions. The division of this region into V_H segments, D segments, and J_H segments is based on homology with the heavy chains binding dextran. The prototype sequence for the V_H and J_H segments is M104E. The prototypes for the D segments are the first sequence in each group. The J segments which do not extend to amino acid 117 are due to incomplete amino acid sequence data and not to shorter J segments.

11 V_H regions (Fig. 1). It is attractive to postulate that the IdX idiotype depends on amino acids at positions 54 and 55. This supposition is supported by the observation that Hdex8, which has greatly reduced IdX reactivity, has a substitution at position 54. Analysis of V_H regions from several additional IdX-negative antibody molecules are in progress to determine whether they also exhibit substitutions at positions 54 and 55 and to test the intriguing possibility that the IdX idiotype may be in part associated with a carbohydrate moiety.

Thus, idiotypes can apparently arise from V segments (IdX) or D segments (IdI). These data on the hybridoma antibodies binding α-1,3 dextran do allow us to assign structural correlates for the cross-reactive (V segment) and individual (D segment) idiotypes of several dextran antibodies. However, an idiotype localised to a particular region (for example, the IdIJ558 to positions 100 and 101) may require particular sequences in still other portions of the V region for its expression (for example, V and J segments like those found in dextran-binding antibodies). Accordingly, the interpretation of genetic mapping of idiotypes is complex. Indeed, one can never be certain what is being mapped—a V segment, a D segment, a J segment, the ability to produce certain somatic variants, or some combination of these.

In an historical context, note that Kabat and coworkers predicted the existence of minigenes for each hypervariable region based on an analysis of the V region amino acid sequences[13,36]. In addition, Capra and Kindt postulated the existence of multiple V coding elements based on an analysis of V_H sequence data and idiotypes[37,38]. If the D segments are encoded by distinct gene segments, they are 'minigenes' that encode the individual idiotypes of murine antibodies binding dextran.

The evolution of split-gene segments and DNA rearrangements

The V_H regions and V_L regions are homologous to one another at the protein level[31,39]. Both V_L and V_H are encoded by V and J gene segments of similar size. This homology implies that the split-gene strategy and the mechanism for rearranging split genes must have arisen before the divergence of light and heavy chains. Indeed, it is attractive to speculate that split genes and mechanisms for their rearrangement evolved before the emergence of the vertebrate immune system, possibly in families of genes coding membrane recognition functions. It will be interesting to determine whether there are other contemporary multigene families using strategies of split genes and DNA rearrangment for the amplification of information[5]. This is discussed elsewhere[40].

The patterns of phenotypic diversity in the V_H regions from antibodies binding α-1,3 dextran have allowed us to make several important conclusions. We can define V_H and J_H segments which are homologous to their light chain counterparts. Diversity in a third region, the D segment, can be explained by a novel somatic mutational mechanism, the existence of a third germ-line (D) gene segment, or the less likely possibility of a large number of J_H gene segments. Antibody diversity appears to arise from several sources: multiple germ-line gene segments, combinational joining of V_H and J_H gene segments and the mechanism for producing D segment diversity which includes extensive nucleotide substitutions as well as the insertion or deletion of multiple residues. Correlations between the V_H sequences and the idiotypes of the antibodies to α-1,3 dextran are possible but there should be caution in the interpretation of genetic mapping studies which use idiotypes. Studies are in progress in our laboratories to expand our analyses of the phenotypic (protein) diversity in the dextran system and to analyse the gene segments encoding the dextran response.

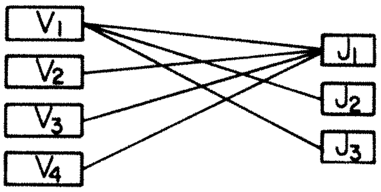

Fig. 4 A diagram indicating the combinational joining of V_H and J_H segments. V_1 to V_4 and J_1 to J_3 are defined in Fig. 2.

A UGA termination suppression $tRNA^{Trp}$ active in rabbit reticulocytes

Alfred I. Geller & Alexander Rich

Department of Biology, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

A $tRNA^{Trp}$ was purified from rabbit reticulocytes which suppresses the UGA termination codon of β-haemoglobin mRNA. Evidence is presented that the β-haemoglobin readthrough protein is found in reticulocyte translations and intact cells. Some natural readthrough proteins perform essential functions; they are synthesised through suppression of UGA or UAG but not UAA termination codons.

THE termination of polypeptide chain synthesis is signalled by the three codons UAG (amber), UAA (ochre) and UGA (opal). Termination is carried out through the activity of release factors which are thought to recognise termination codons and release the nascent polypeptide chain[1-3]. In some cases, termination is suppressed by a tRNA which recognises one of the termination codons and inserts an amino acid[4]. The ribosome then continues adding amino acids to the nascent chain until it encounters the next termination codon. Proteins which are synthesised in this manner are called 'readthrough' proteins and the tRNAs which recognise the termination codons are called suppressor tRNAs. Suppressor activity is of two types; naturally occurring and induced through mutagenesis. Natural suppression seems to be a mechanism for producing proteins which, while related to other proteins, nonetheless perform distinct and essential functions. Naturally occurring suppression has been largely associated with viral infection in prokaryotic as well as eukaryotic systems. The example of natural readthrough which has been studied in greatest detail is Qβ infection of *Escherichia coli*. The coat protein gene has a UGA termination codon. Wild-type *E. coli* $tRNA^{Trp}$ misreads the UGA codon at a low frequency, producing a coat readthrough protein[5-8] which is required for infection by Qβ[9]. An analogous situation may exist in bacteriophage λ infection of *E. coli* where the UGA termination codon of the O protein is read through[10,11]. Filamentous bacteriophages may also require UGA readthrough[11]. Recently, a readthrough protein produced by suppression of a UAG termination codon has been detected during the infection of tobacco plants by tobacco mosaic virus (TMV)[12]. However, this suppressor activity has not yet been associated with a particular tRNA.

Here we report a UGA suppressor activity in rabbit reticulocytes which produces a β-haemoglobin readthrough protein. A purified rabbit reticulocyte $tRNA^{Trp}$ dramatically enhances UGA suppression in the reticulocyte lysate. Furthermore, evidence is presented which strongly suggests that the UGA suppressor activity is active within intact reticulocyte cells producing very small amounts of the β-haemoglobin readthrough protein. This is the first demonstration of naturally occurring readthrough in a non-viral system.

Detection of suppression

Suppressor tRNAs from prokaryotic systems have been well characterised and sequenced. Although yeast suppressor tRNAs function in higher eukaryotic lysates[13,14] prokaryotic suppressor tRNAs often do not work in eukaryotic systems[13]. Our assumption was that this was due to the inability of eukaryotic aminoacyl tRNA synthetases to aminoacylate these tRNAs efficiently. Accordingly, we devised an *in vitro* system in which a purified prokaryotic tRNA and its purified cognate prokaryotic synthetase are added to a eukaryotic cell-free protein synthesising system. The well characterised rabbit reticulocyte system was used in which haemoglobin is the predominant (90–95%) product synthesised. Figure 1 shows reticulocyte translations using ^{35}S-methionine analysed on an SDS gel. Lane *a* shows the effect of adding the *E. coli* UGA suppressor without synthetase while lane *b* shows the effect of adding the UGA suppressor tRNA and *E. coli* Trp synthetase. A new band (*B*) appears which is somewhat larger than the two globin chains (Hb). Lane *c* shows the effect of adding an *E. coli* UAA suppressor tRNA and *E. coli* Tyr synthetase. A different protein (A) is produced which migrates more slowly than haemoglobin. Lane *d* shows the effect of adding the UAA suppressor tRNA without synthetase. Lane *e* is a control with no additions. The readthrough proteins A and B have distinct mobilities even when mixed together (data not shown).

α-Haemoglobin mRNA terminates in a UAA codon and the next termination codon in phase occurs 21 codons downstream[15]. This suggests that band A seen in Fig. 1 is the α-haemoglobin readthrough protein. Rabbit β-haemoglobin mRNA terminates in a UGA termination codon. The next termination signals, two UAAs in tandem, occur 22 codons later[16]. This suggests that band B in Fig. 1 is the β-haemoglobin readthrough protein. α- And β-haemoglobin readthrough proteins have also been synthesised when the appropriate yeast suppressor tRNAs are added to a wheat-germ extract[17]. In further experiments not shown here, an *E. coli* UAG suppressor tRNA and its purified tyrosine synthetase were added to the reticulocyte lysate but no readthrough bands were detected. The UAG suppressor was shown to function in the reticulocyte lysate using an RNA from a Qβ mutant (*am* − 1) which has a UAG nonsense mutation in the synthetase gene[14].

We observed faint bands in all of the lanes of Fig. 1 at the same position as the putative β-haemoglobin readthrough protein. This suggested that there might be natural readthrough of the UGA termination codon of rabbit β-haemoglobin mRNA. Before proceeding further, we carried out additional analysis of the readthrough band to demonstrate that it is in fact the β-haemoglobin readthrough protein. α- And β-haemoglobin chains and the β-haemoglobin readthrough protein were purified then subjected to tryptic digestion[18]. The results are shown in Fig. 2 and a diagram shows the position of the methionine-containing tryptic peptides in both α- and β-haemoglobin and their readthrough proteins[15,16]. α-Haemoglobin has one methionine-containing tryptic peptide composed of 9 amino acids. There are no additional methionines in its readthrough protein. β-haemoglobin has one methionine-containing tryptic peptide composed of 19 amino acids. That peptide, which ends in lysine, is followed by the sequence

0028–0836/80/010041—06$01.00

Val-Lys at its C terminus; in the case of incomplete cleavage at the first lysine residue, one may get a peptide containing 21 amino acids. The readthrough protein of β-haemoglobin has an additional methionine-containing tryptic peptide, 7 amino acids in length[16].

The tryptic peptides were analysed by electrophoresis at *p*H 3.5. Lane *a* of Fig. 2 has ^{35}S-methionine alone, lane *b* contains the tryptic digest of β-haemoglobin. The direction of migration is to the left (towards negative) and two spots are seen. This suggests that the slower spot contains 19 amino acids while the faster spot contains 21 amino acids, resulting from incomplete cleavage at the C-terminal lysine. Incomplete cleavage results in the addition of Val-Lys to the peptide and a doubling of its positive charge at *p*H 3.5. This assignment is strengthened by the observation that longer digestion periods yield more of the slower spot. The tryptic digest of β-haemoglobin was also analysed by chromatography[18]. The results of this experiment (not shown) yielded two spots which migrated at positions very close to each other, suggesting the general properties of these two peptides, including both length and chemical characteristics, are very similar. This is consistent with our identification of the second minor peptide as arising from incomplete digestion by trypsin. Lane *c* shows the tryptic digest of α-haemoglobin which yields one major spot. Lane *f*, a mixture of tryptic digests of α- and β-haemoglobin show three spots. The tryptic peptides of the putative β-haemoglobin readthrough protein are shown in lane *d*. This produced three spots, two of which migrated at the same position as the β-haemoglobin spots and one additional spot migrating between the two. Lane *e* shows a mixture of the tryptic digests of both α- and β-haemoglobin and the β-haemoglobin readthrough protein. Four spots are now observed. The conclusion from this experiment is that band B in Fig. 1 is indeed the β-haemoglobin readthrough protein as shown by the appearance of an additional methionine containing tryptic peptide which is expected in view of the mRNA sequence after the UGA termination codon.

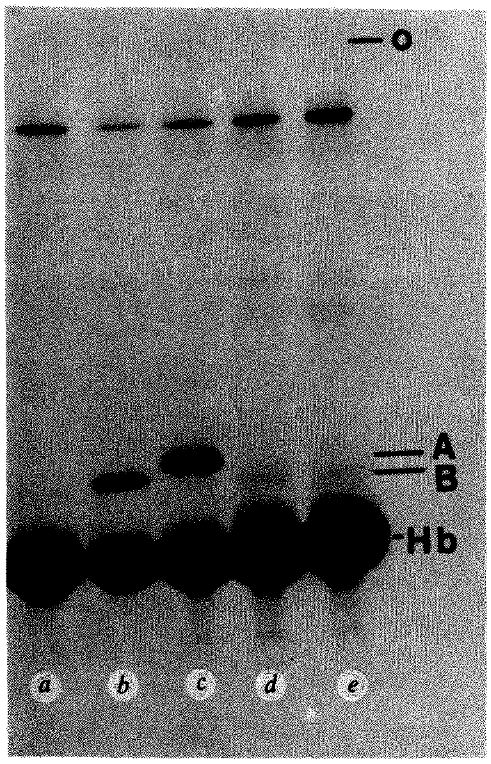

Fig. 1 Autoradiogram of rabbit reticulocyte lysates incubated with ^{35}S-methionine and analysed on an SDS gel. *E. coli* suppressor tRNAs were isolated from *E. coli* DB 6437 Sup C (UAA)[33] and LS 849 Su^{7+} (UGA)[34] (provided by David Botstein). LS 849 was grown as described in ref. 35. An S-30 supernatant was prepared[36] and then centrifuged at 100,000*g* for 5 h. The supernatant was extracted with phenol saturated with 10 mM Tris-HCl (*p*H 7.5), 10 mM $MgCl_2$, 30 mM NH_4Cl. After deacylation[37] and exhaustive dialysis against 200 mM NaAc (*p*H 5.0), the tRNA$^{\mathrm{Tyr}}$ (ref. 38) and tRNA$^{\mathrm{Trp}}$ (refs 23, 24) were purified and stored at −60 °C. *E. coli* Tyr aminoacyl tRNA synthetase[39] (Tyr R.S.) and *E. coli* Trp aminoacyl tRNA synthetase[23] (Trp R.S.) were gifts from P. Schimmel and K. Muench respectively. One part haemin and 0.4 parts creatine phosphokinase[40] were added to 100 parts reticulocyte lysate[41]. Reticulocyte translation solution (25 μl) contained 0.5 mM spermidine, 8 mM creatine phosphate, 25 μM amino acids except methionine, 2 mM dithiothreitol (DTT), 20 mM HEPES (*p*H 7.6), 0.65 mM $MgAc_2$, 80 mM KAc, 5 μl (5 mCi ml^{-1}) ^{35}S-methionine (Amersham), and 10 μl reticulocyte lysate. 5 μg tRNA and 0.2 μg aminoacyl tRNA synthetase were added as indicated below. Reaction mixtures were incubated at 37 °C for 1 h and stored at −20 °C for subsequent use. Reaction mixtures (1 μl) contained approximately 100,000 trichloroacetic acid (TCA) precipitable counts. Aliquots of 2 μl were loaded into each lane of a 15–20% linear gradient polyacrylamide SDS gel[42]. The gel was run for 1 h after the bromophenol blue (BPB) tracking dye ran off the bottom. The gel was stained, destained, fluorographed[43] and then exposed to XR-5 film for 1 d. Lane *a*, Su^{7+} (UGA) tRNA; lane *b*, Su^{7+} (UGA) tRNA and *E. coli* Trp R.S.; lane *c*, Sup C (UAA) and *E. coli* Tyr R.S.; lane *d*, Sup C (UAA) tRNA; lane *e*, no additions. The origin is marked O.

UGA suppression in reticulocyte lysate

Experiments were carried out to detect natural readthrough producing the β-haemoglobin readthrough protein. Two-dimensional gel electrophoresis[19] was used to separate the various products made by the reticulocyte lysate. Figure 3*a* shows a 12-hour exposure of a two-dimensional gel of a translation with *E. coli* UGA suppressor tRNA (hereafter all translation with *E. coli* suppressor tRNA also contained the appropriate *E. coli* synthetase). The small spot indicated by the vertical arrow is the β-haemoglobin readthrough protein while the larger spots below it are haemoglobin chains. Figure 3*b* shows a 1-week exposure of the same gel. Figure 3*C* is a 1-week exposure of a two-dimensional gel of a translation with no additions. A faint spot appears at the same position as the β-haemoglobin readthrough protein. This gel also revealed a few proteins with the same molecular weight as the β-haemoglobin readthrough protein but very different isoelectric points. These proteins prevented the purification of enough natural β-haemoglobin readthrough protein to permit tryptic analysis.

To ensure identification of this weak spot another electrophoretic experiment was carried out; a two-dimensional gel was run using isoelectric focusing in the first dimension and an acid-urea gel in the second[20]. The β-haemoglobin readthrough protein was detected by autoradiography. The gel fragment containing this spot was excised, rehydrated, and loaded on to an SDS gel for further analysis. A gel slice containing haemoglobin was excised from an SDS gel to run in the system as a marker. The control in Fig. 3*D*, lane *a*, contains two bands, one of which is haemoglobin. Since all the protein in lane *a* is haemoglobin, the second band is likely to be a dimer of two haemoglobin chains. Crosslinking could have occured during either staining, destaining, drying or autoradiography. Lane *b* came from a translation containing the *E. coli* UGA suppressor analysed as described above; in addition to haemoglobin and haemoglobin dimers, it contains the β-haemoglobin readthrough protein labelled B. Lane *c* was a translation with no additions analysed on a two-dimensional gel. This lane also shows a weak band which co-migrates with the β-haemoglobin readthrough protein. This evidence strongly suggests that there is a low level of natural readthrough of the UGA termination codon of β-haemoglobin mRNA in the rabbit reticulocyte lysate.

Readthrough proteins in rabbit reticulocyte cells

An experiment was carried out to detect synthesis of the β-haemoglobin readthrough protein in intact rabbit reticulocyte cells. Reticulocytes were incubated in a cell culture medium in the presence of radioactive amino acids[21]. The proteins were separated on two-dimensional gels[19]. Figure 4*a* shows an analysis of the mixture of the incubation and a translation with

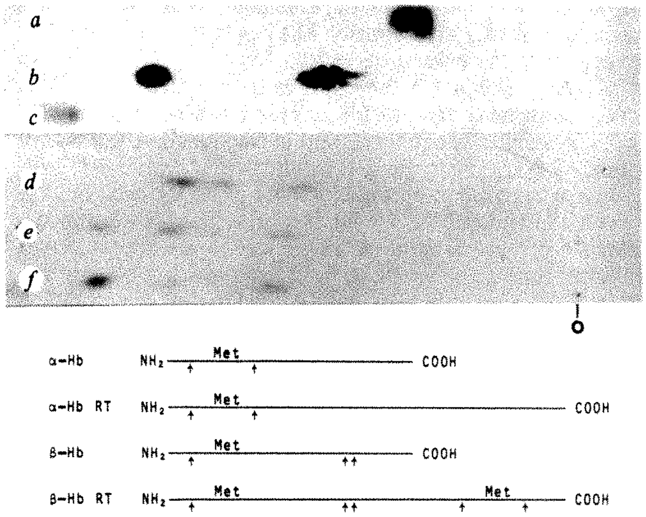

Fig. 2 Autoradiogram of tryptic digestion of various haemoglobin chains. At the bottom is a diagram showing the α- and β-haemoglobin (Hb) chains as well as their readthrough (RT) proteins. The vertical arrows indicate the positions of tryptic digestion sites around methionine-containing peptides. A 25-μl translation mixture was run on a 15% polyacrylamide SDS phosphate gel[44] for 20 h at 80 mA to separate ^{35}S-methionine-labelled α- and β-haemoglobin. A 25-μl translation mixture with Su^{7+} (UGA) tRNA and *E. coli* Trp R.S. was run on an SDS gel[42] as in Fig. 1 to purify the putative β-haemoglobin readthrough protein. Gels were autoradiographed to locate the protein. Samples were prepared and digested with trypsin as described[18] with the following modifications; 4 μl of 25 mg ml^{-1} bovine serum albumin was added to the β-haemoglobin readthrough protein sample; the α- and β-haemoglobin samples required no carrier. After the final lyophilisation, the samples were taken up in 20 μl H_2O. The tryptic peptides were analysed by electrophoresis on cellulose-coated thin layer plates for 90 min at 1,000 V, 25 mA in pyridine : acetic acid : H_2O, 1 : 10 : 100 (*p*H 3.5). The plate was immersed in PPO-β-napthalene[45] and then exposed to film for 2 d except for lane *c* which was exposed for 1 d. Lane *a*, 3,000 c.p.m. ^{35}S-methionine. The following tryptic digests: lane *b*, 3,000 c.p.m. β-haemoglobin; lane *c*, 3,000 c.p.m. α-haemoglobin; lane *d*, 1,500 c.p.m. β-haemoglobin readthrough protein; lane *e*, 500 c.p.m. α-haemoglobin and 500 c.p.m. β-haemoglobin and 500 c.p.m. β-haemoglobin readthrough protein; lane *f*, 750 c.p.m. α-haemoglobin and 750 c.p.m. β-haemoglobin. The origin is marked O.

an *E. coli* UGA suppressor; the 1-week exposure shows a well developed spot in the position of the β-haemoglobin readthrough protein as indicated by the arrow. Figure 4*b* is a 1-month exposure of just the incubation of intact cells; several additional spots appeared after the longer exposure. There is a small spot which migrates at the position of the β-haemoglobin readthrough protein. Because of the low level of the putative β readthrough protein in intact cells, no further analysis was attempted. It seems likely that there is a low level of production of the β-haemoglobin readthrough protein in intact reticulocyte cells.

tRNA fractionation and suppressor activity

The results presented above suggested that there might be a tRNA in the reticulocyte cell which suppresses the UGA termination codon. Reticulocyte tRNA was fractionated on BD cellulose[22], widely used in tRNA purification, to purify this activity. As shown in the graph at the top of Fig. 5, the bulk of the tRNA emerges in the first third of the column. The assay shown for tryptophan acceptor activity has a maximum near fraction 13, and a leading shoulder in fractions 5–8. Each of these fractions was precipitated and then redissolved in H_2O. A sample of 4 μg of tRNA from each fraction was added to a 25 μl reticulocyte translation representing a 10–20% increase in the amount of tRNA in the reaction. The results are shown at the bottom of Fig. 5. The lanes marked Su$^+$ and Su$^-$ were controls with the *E. coli* UGA suppressor added and with no additions, respectively. The Su$^+$ lane shows the β-haemoglobin readthrough protein which is enhanced in fractions 5–8. In fraction 6 a number of other bands are also enhanced for an unknown

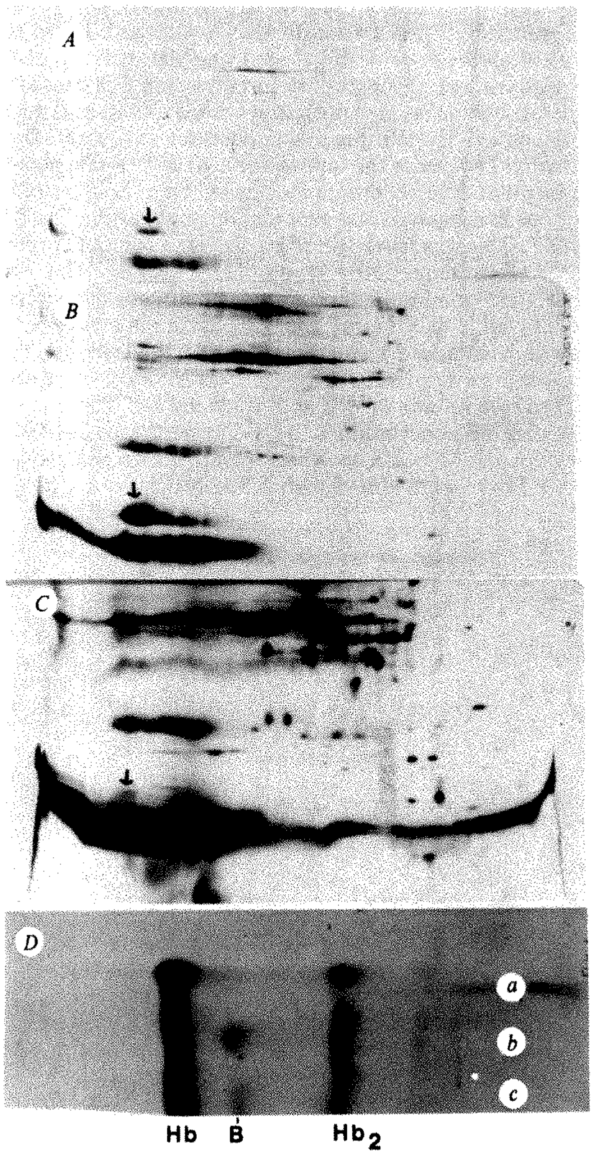

Fig. 3 Autoradiograms of ^{35}S-methionine-labelled reticulocyte translation mixtures analysed in various gel systems. Two-dimensional gels[19] were run with *p*H 6–8 and *p*H 3–10 ampholytes in the ratio of 4:1 in isoelectric focusing. The second dimension (vertical) was a 15–20% linear gradient polyacrylamide SDS gel. The gel was treated as in Fig. 1. *a*, 5×10^5 c.p.m. of a translation mixture with Su^{7+} (UGA) tRNA and *E. coli* Trp R.S. The film was exposed for 12 h. *b*, 1-week exposure of gel *a*. *c*, 1.5×10^6 c.p.m. of a translation mixture with no additions. The film was exposed for 1 week. *d*, Readthrough spots were isolated from isoelectric focusing acid-urea two-dimensional gels and run on SDS gels. Isoelectric focusing tube gels were run as above[19]. The gels were equilibrated in buffer O′ (5% HAc, 10% glycerol) for 30 min and then stored at −60 °C or used immediately. Slab gels of 15% polyacrylamide acid-urea[20] were pre-run for 1 h at 125 V. The equilibrated tube gels were loaded on top of acid-urea gels and overlaid with freshly made 1% agarose in buffer O′ in the same manner as the second dimension of two-dimensional O'Farrel gels[19]. Gels were run for 20 h at 125 V, destained, dried and autoradiographed for 1 week. The appropriate gel cubes were located, excised, rehydrated in buffer O[19] for 30 min, and then analysed on an SDS gel[42] as in Fig. 1. Only the SDS gel is shown: lane *a*, the haemoglobin band from a translation mixture was isolated from an SDS gel run as in Fig. 1. The gel slice was rehydrated in buffer O and loaded on to the SDS gel. The control haemoglobin now appears as two spots, probably due to dimerisation. Lane *b*, the β-haemoglobin readthrough spot from 5 μl of a translation mixture with Su^{7+} (UGA) tRNA and *E. coli* Trp R.S. was isolated from an isoelectric focusing acid-urea two-dimensional gel. Lane *c*, 25 μl of a translation mixture with no additions was assayed in a way analogous to *b*. The gel was exposed to film for 2 months.

reason. These bands are all detected in reticulocyte translations with no additions on longer exposures; the bands are resistant to RNase digestion (results not shown) so they are not polypeptide chains prematurely released with tRNA attached. From this experiment alone, it could be argued that the increase of the β-haemoglobin readthrough protein in fraction 6 is caused by the general enhancement of protein synthesis activity and not by a suppressor activity. We therefore undertook to separate these two activities and purify the suppressor activity to homogeneity.

The fact that the enhancement occurred on a shoulder of the $tRNA^{Trp}$ peak suggested that suppression might be mediated by a $tRNA^{Trp}$. This was investigated by a second column chromatography of aminoacylated tryptophanyl-$tRNA^{Trp}$ on BD-cellulose. BD-cellulose has a strong affinity for planar ring molecules and binds reticulocyte tryptophanyl-$tRNA^{Trp}$ because of the attached aromatic amino acid; this is the standard method for purifying *E. coli* $tRNA^{Trp}$ (refs 23, 24). As shown in Fig. 6, the column was loaded with fractions 5–8 from the first column after aminoacylation with ^{3}H-Trp. Fractions 3–13 were eluted with 0.8 M NaCl to wash off all uncharged tRNAs. Fractions 14–18 were eluted with 1.5 M NaCl, 20% EtOH to wash all tRNA off the column. The final wash resulted in a significant peak of optical density. The peak of ^{3}H-Trp-$tRNA^{Trp}$ emerged from the column largely in fractions 14 and 15. No Trp-$tRNA^{Trp}$ eluted off the column before that point. The fractions were also assayed for tryptophan-accepting activity, (Fig. 6). A small amount was found in fractions 1–13, however fractions 14–17, comprising the final wash, contained large amounts of tryptophan-acceptor activity. Since the ester linkage between Trp and $tRNA^{Trp}$ is labile with a half life of approximately 6 h in these conditions, a significant amount of $tRNA^{Trp}$ is released during the purification process which took approximately 10 h. Almost half the $tRNA^{Trp}$ came off with the final wash.

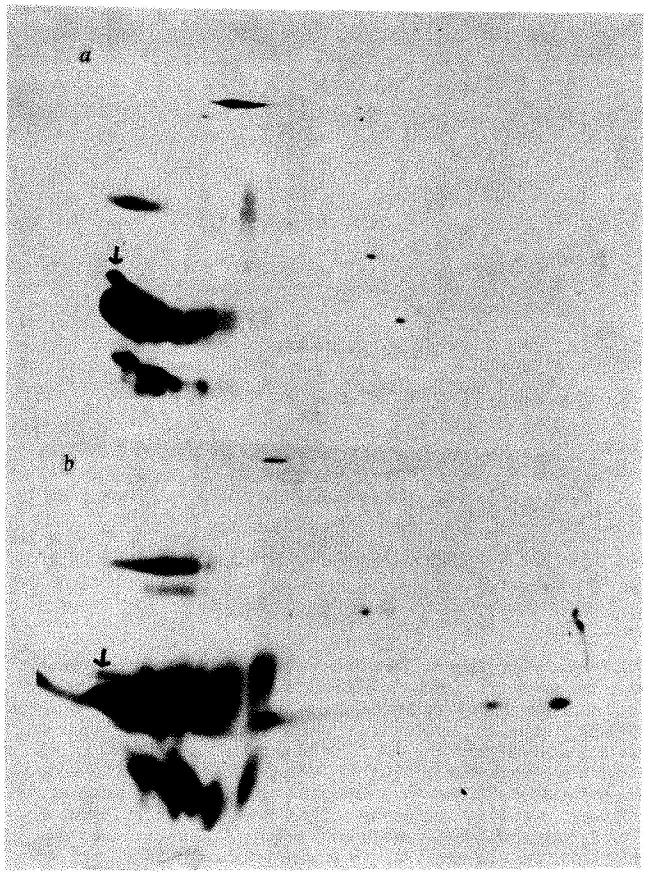

Fig. 4 Autoradiographs of two-dimensional gels analysing labelled reticulocyte proteins. Reticulocytes were incubated[21] with the following modifications: the 10-ml incubation mixture contained Krebs–Ringer phosphate, 0.001% heparin, 2 ml dialysed calf serum, 0.2 mM cysteine, 2 mM glutamine, 0.05 mM tryptophan, 0.2 mM asparagine, 10 mM 2-mercaptoethanol (2-ME), 1 mg ml^{-1} glucose, 1.8 mCi ^{35}S-methionine and 250 μCi of a ^{3}H-labelled amino acid mixture (Amersham). After the incubation, the cells were centrifuged at 15,000g for 5 min, washed once in Krebs–Ringer phosphate, centrifuged, lysed in an equal volume of H_2O containing 10 mM phenylmethylsulphonyl fluoride and then centrifuged for 20 min to remove cell membranes. The supernatant was precipitated with 10% TCA for 30 min at 0 °C and centrifuged for 10 min. The pellet was redissolved in one volume of 10% glycerol, 10% SDS, 2 mm EDTA, 1 M DTT, 100 mM Tris-HCl (*p*H 7.5), 0.1% BPB and titrated to *p*H 7.0 with 3 M NaOH. The sample was boiled for 5 min and stored at −20 °C for subsequent use. Two-dimensional gels[18] were run as in Fig. 3. *a*, 7.2×10^4 c.p.m. of the intact cell incubation plus 2×10^5 c.p.m. of an *in vitro* translation mixture with Su^{7+} (UGA) tRNA and *E. coli* Trp R.S. The film was exposed to the gel for 1 week. *b*, 2×10^5 c.p.m. of the intact cell incubation. The film was exposed to the gel for 1 month.

The autoradiogram shown in Fig. 6 shows the effect of these various fractions on translation in the reticulocyte system. There is a small enhancement of readthrough in many of fractions 1 to 15. However, a very large increase in readthrough is observed in fractions 16 and 17. Interesting, in fractions 14–17, there is high tryptophan-acceptor activity. Figure 5 shows the reticulocyte suppressor $tRNA^{Trp}$ and the nonsuppressing $tRNA^{Trp}$ were incompletely separated; it is likely that the second column achieved a better separation. The total radioactivity incorporated in translations of fractions 16 and 17 in Fig. 6 was somewhat less than that found in translations containing other fractions. This is probably associated with a higher amount of salt in that fraction which was not fully washed out. Longer exposure of the autoradiogram in Fig. 6 revealed that the general stimulatory activity migrated with the major peak of tRNA, fractions 2–5. A densitometer tracing of the optical density in the β-haemoglobin readthrough protein band compared to the haemoglobin band indicated that the intensity of the bands is approximately equal. The haemoglobin band contains a mixture of both β and α chains, while the readthrough band contains only β-haemoglobin readthrough protein. This suggests that a very high efficiency of readthrough is produced by fractions 16 and 17. It appears more efficient than the *E. coli* UGA suppressor (lane Su$^+$). Electrophoresis on two-dimensional gels showed that the readthrough protein synthesised in translations containing fractions 16 and 17 comigrated with the β-haemoglobin readthrough protein and migrated differently from the α-haemoglobin readthrough protein in both dimensions (results not shown).

Discussion

Analysis of translations with no additions revealed a small amount of a peptide which had the identical mobility as the β-haemoglobin readthrough protein in three different electrophoretic systems. This strongly suggested the presence of a UGA suppressor tRNA in the reticulocyte. This was examined by fractionating reticulocyte tRNA and isolating a peak which enhanced the production of the β-haemoglobin readthrough protein. This was identified as a $tRNA^{Trp}$ by separating tryptophanyl-$tRNA^{Trp}$ from all other tRNAs. Proteins from intact rabbit reticulocyte cells incubated with ^{35}S-methionine were analysed by two-dimensional gel electrophoresis. A small spot was detected in the same position as authentic β-haemoglobin readthrough protein. Although this identification does not establish proof, coupled with the isolation of a tRNA from the reticulocyte cell which reads the UGA termination codon, this result strongly suggests that we have detected a low level of β-haemoglobin readthrough protein in the intact reticulocyte cell.

The β-haemoglobin readthrough protein appears to be stable in *in vitro* incubations. Additional incubation in the presence of glucose and/or ATP did not degrade the β-haemoglobin readthrough protein nor did its position change in two-dimensional gel electrophoresis which, for example, might occur as a result of glycosylation. The readthrough activity in the TMV[12] and Qβ[25] systems are sensitive to changes in Mg^{2+} concentration. The concentrations of Mg^{2+}, K^+ or Na^+ have little influence on the amount of β-haemoglobin readthrough protein produced (data not shown). The material which produces the readthrough is likely to be RNA as KOH treatment abolishes production of the β-haemoglobin readthrough protein. The position of this RNA molecule on a column changes after it has been aminoacylated with tryptophan. It is on this basis that we feel confident that there is a reticulocyte $tRNA^{Trp}$ which reads the UGA termination codon. It has also been shown that $tRNA^{Trp}$ reads UGA in other systems[5-8,26].

The tRNA species which has been purified is highly active in producing the β-haemoglobin readthrough protein; it is not likely that it is operating by making occasional mistakes. This tRNA is now being purified further with a view to determining its complete nucleotide sequence. This will allow us to determine whether it is reading UGA because of a mutation in the anticodon which makes it complementary to UGA or because of a difference in nucleotide modification from the more abundant reticulocyte nonsuppressing $tRNA^{Trp}$. Methylation and other nucleotide modifications have been shown to alter the reading abilities of other tRNAs[4]. Misreading in this case requires an A · C base pair, therefore it cannot be described as wobble misreading.

Broadly considered, there are two different types of termination suppression. One is induced suppression, produced by mutagenesis, which has been studied extensively in prokaryotic and lower eukaryotic systems. A nonsense mutation produces a termination codon in the middle of the structural protein and a second mutation produces a termination suppressor tRNA which reads the termination codon restoring the original polypeptide. The second class are natural suppressors; these occur in the wild-type organism. These have not been studied extensively and our knowledge is relatively meagre. The best characterised example of naturally occurring suppression is the coat readthrough protein which is synthesised during infection of *E. coli* cells by Qβ virus; wild-type *E. coli* $tRNA^{Trp}$ suppresses the UGA termination codon of the coat protein[5-8]. The readthrough protein, produced at low frequency, is essential for the production of infective Qβ virions[9]. The function of the readthrough protein is not known. Another example of naturally occurring UGA suppression is found in bacteriophage λ infection of *E. coli* where the O protein is read through producing the readthrough protein O′ (refs 10, 11). As in Qβ infection, the O′ protein appears to be essential for infection[11]. Very little is known about natural readthrough in eukaryotic systems. A UAG (amber) suppressor tRNA may be used in the translation of a tobacco mosaic virus mRNA[12]. Addition of yeast amber suppressor tRNA to the reticulocyte system enhances the production of a 160,000 MW protein and diminishes a 110,000 MW protein. These proteins both have the same N-terminal sequence and have been isolated from the infected plant leaves. The 160,000 MW protein is produced in the rabbit reticulocyte lysate suggesting that it has a natural UAG suppressor activity. A UAG suppressor activity has also been inferred in the production of the polymerase protein in murine leukaemia virus infection[27,28] but appears not to be used in the related Rous sarcoma virus infection[29].

The UGA suppressor activity we have demonstrated in the reticulocyte is the first example of a natural suppressor activity not associated with viral infection. It suggests that naturally occurring termination suppressors may be active in non-viral systems. Further analysis will be necessary to determine the extent to which these naturally occurring suppressors are found in other systems. Preliminary results from experiments involving the addition of fractionated yeast tRNA to the reticulocyte lysate and translations of rabbit reticulocyte mRNA in the wheat-germ system indicate a UGA suppressor activity in both these sources.

The existence of haemoglobin molecules with C-terminal additions is not unknown. In humans, mutations are found in the termination codons of both α- and β-haemoglobin mRNA (haemoglobins Constant Springs and Tak[30]). Apparently, the addition of a peptide at the C terminus does not grossly interfere with physiological function although not much is known about other effects it may have.

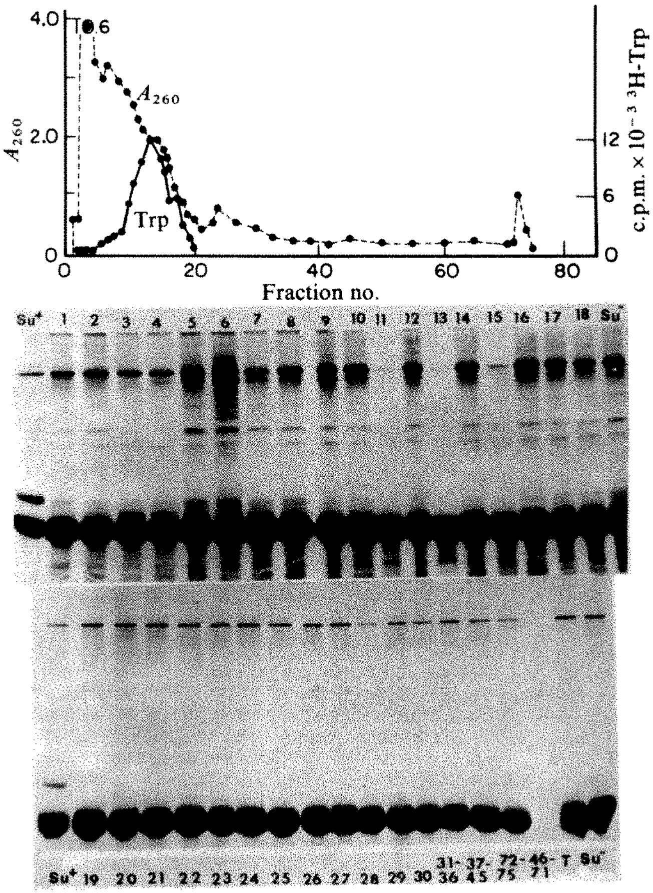

Fig. 5 Fractionation of reticulocyte tRNA on BD-cellulose and an assay for the production of readthrough proteins. Reticulocyte lysate[41] was centrifuged at 100,000*g* for 5 h. The supernatant was extracted with phenol saturated with 0.15 M NaCl, 10 mM Tris HCl (*p*H 7.5), 1 mM EDTA, then deacylated[37] and dialysed overnight against 200 mM NaAc (*p*H 5.0). The RNA was loaded on to a 12-ml BD-cellulose column[22] in 200 mM NaCl and developed with a linear 500 ml gradient from 0.4 to 0.9 M NaCl (fractions 1 to 71). This was followed by a 10% EtOH, 1 M NaCl wash (fractions 72 to 75). All column buffers contained 25 mM Tris-HCl (*p*H 7.5), 10 mM $MgCl_2$. Yeast Trp R.S. was isolated: 1 lb of baker's yeast was lysed with toluene[46] and then centrifuged at 13,000*g* for 40 min. The supernatant was made 100 mM Tris-HCl (*p*H 7.5), 30 mM 2-ME, 10 mM $MgCl_2$ and the *p*H was adjusted to 7.5 with 2 M NaOH. 0.1 volume of 1 M BaCl was added and the solution was centrifuged for 30 min. The supernatant was made 20 mg ml^{-1} in streptomycin sulphate and centrifuged for 30 min. The supernatant was precipitated with $(NH_4)_2SO_4$ (ref. 46) and the pellet redissolved with and dialysed against 20 mM $KHPO_4$ (*p*H 7.0), 1 mM DTT and stored in 50% glycerol at −20 °C. Charging assays were performed as described in ref. 46 on 8 μl of each fraction for Leu, Tyr, Lys, Gly and Trp. Only the Trp acceptance curve is shown. Fractions were precipitated, washed twice with 66% EtOH, taken to near dryness under a vacuum, and redissolved in H_2O to a concentration of 2 μg μl^{-1}. 2 μl were added to a 25-μl reticulocyte translation mixture which was incubated and analysed as in Fig. 1. The lane numbers refer to translations of the various fractions. The Su^+ lane contained Su^{7+} (UGA) tRNA and *E. coli* Trp R.S., the Su^- lane had no additions. Lane 46–71 was inhibited by excess salt. Lane T contained a reaction with unfractionated reticulocyte tRNA. The top gel was exposed to film for 4 d and the bottom gel for 3 d.

A review of the literature on termination codons and natural suppressor tRNAs suggests that there are significant differences between the three termination codons. The UAA (ochre) codon has no known naturally occurring suppressor tRNAs. In the haemoglobin system, we have an assay for the presence of UAA readthrough but no activity is found in reticulocyte tRNA. Induced UAA suppressor tRNAs in prokaryotic systems are found to be detrimental causing a doubling of the generation time[4]. It is possible that efficient UAA suppressors might be lethal. However, cells with either UGA or UAG suppressor tRNAs appears to be healthy and indeed some readthrough proteins made by suppressing these two termination codons seem to be used in natural systems.

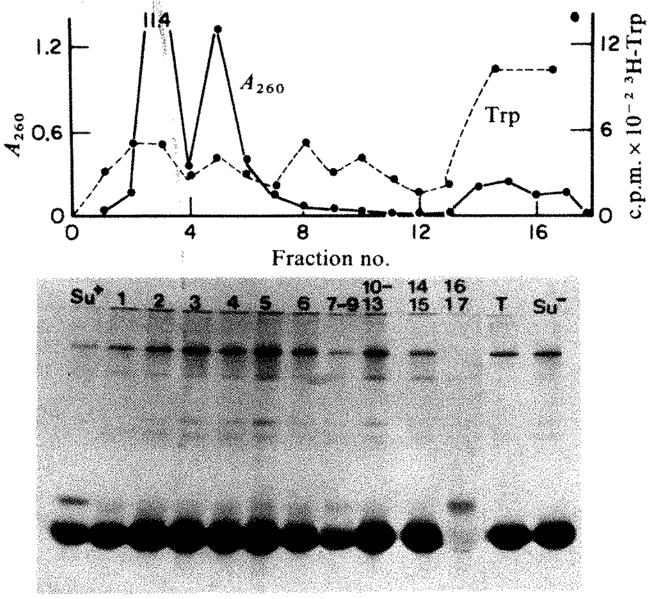

Fig. 6 Further fractionation of fractions 5 to 8 of Fig. 5 after aminoacylation with tryptophan. Yeast synthetase was passed over a G-100 column to remove any remaining yeast tRNA. Fractions 5 to 8 from Fig. 5 were charged with ^{3}H-Trp[46]. The reaction was stopped with the addition of 1/10 volume 2 M NaAc (*p*H 5.0) and 1 volume phenol saturated with 50 mM NaAc (*p*H 5.0). All operations were at 4 °C. The tRNA was precipitated, washed once with 66% EtOH and redissolved in 2 ml 0.4 M NaCl and loaded on to a 12-ml BD column[22]. The first half of fraction 1 represents the effluent from loading the sample. The last half of fraction 1 and fraction 2 were eluted with 0.4 M NaCl. Fractions 3 to 13 were eluted with 0.8 M NaCl and fractions 14 to 18 were eluted with 1.5 M NaCl, 20% EtOH. All column buffers contained 10 mM $MgCl_2$ and 50 mM NaAc (*p*H 5.0). 50 µl of each fraction was TCA precipitated. The ^{3}H-Trp tRNA^{Trp} peak (not shown) was primarily in fraction 14 but also in fractions 15 to 17. None was detected before fraction 14. 8 µl of each fraction was assayed for Trp acceptance activity[46] as shown in the graph. Fractions 14 –15 and 16–17 were pooled before the assay. The fractions were then assayed for suppression activity as in Fig. 5. The film was exposed for 2 d.

Evolutionary implications of termination suppression

The difference in the way nature uses termination codons suggests a rationale for the existence of three termination codons in the genetic code. It is possible that termination codons have different meanings. Perhaps the codon UAA means that translation must 'always stop' and perhaps there are very few (or no) exceptions to this in normal cells. The codons UAG and UGA may mean 'usually stop'. However, naturally occurring tRNAs will occasionally read UAG or UGA, resulting in the production of natural readthrough proteins. In addition, double stop signals are used to ensure the complete termination of protein synthesis after a given codon and are abundant in prokaryotic systems[31]. A low level of natural suppressor would be unable to read through a double stop system at a significant frequency. The selective utilisation in mRNAs of the three different termination codons and multiple stop signals allows the systems to have complete stop signals as well as partial or controllable stop signals. Nature has thus achieved a measure of control of gene expression at the level of termination. Diversification and evolutionary experimentation can then be carried out; occasionally a peptide is added to the C terminus of a selected protein. The resulting readthrough protein may perform a unique and perhaps essential function.

We suggest that natural readthrough is used occasionally to create proteins in which two different polypeptide chains are joined together. This ability may be used in a selective fashion, perhaps to control key biological processes. It would be of interest, for example, to see whether suppressor tRNAs are synthesised at key points in cellular development or perhaps during oncogenic conversion. Development of this process has provided an opportunity for exploiting the effects of producing novel proteins by joining different segments.

Is it possible that this type of experimentation was found to be very useful in the evolution of biological systems? Perhaps natural readthrough was a precursor to a more complex system of synthesising proteins by bringing together different polypeptides: RNA splicing[32]. The power of the splicing system, in contrast to the readthrough system, is that the segments to be joined together need not be contiguous in the genome of the organism. Splicing is also far more efficient than readthrough. Nonetheless, the net result of splicing and natural readthrough may be quite similar. We suggest that the utility of using occasional readthrough proteins which join together different polypeptide segments may have some of the positive features which are present in the more sophisticated RNA splicing mechanism which plays a significant role in the expression of genetic information in eukaryotic cells.

Superclusters and galaxy formation

Jaan Einasto, Mihkel Jôeveer & Enn Saar

Tartu Astrophysical Observatory, Tôravere 202444, Estonia, USSR

Most galaxies and rich clusters of galaxies[1] are concentrated in superclusters, and there are great distances between superclusters[2–6]. In this paper we study the structure of superclusters using Zwicky clusters[7] as principal tracers of the large-scale structure of the Universe. Our study is restricted to the southern galactic hemisphere.

Using Huchra's compilation of available redshifts of galaxies we have found mean redshifts of Zwicky clusters of distance class 'near' in the region 22 h $\le \alpha \le$ 4 h. Of the 88 clusters in the area considered, redshifts have been measured for 56. The redshifts of the remaining 32 clusters have been estimated on the basis of luminosity function and apparent diameter. The distribution of clusters in the sky in two redshifts intervals is given in Fig. 1.

The prominent triangle-shaped aggregate seen in Fig. 1*a* is the Perseus supercluster. Its richest cluster A426[1], is located at the northern tip of the supercluster. Further, rich clusters are situated in the western and southern tips—the Pegasus cluster U487[8] and A194, respectively. Other clusters form chains joining the tips of the supercluster. A chain is located close to the Milky Way, forming the northern boundary of the Andromeda supercluster.

In Fig. 1*b* two superclusters can be seen: the Pegasus supercluster in the right-hand section of the figure and the Cetus supercluster in the lower left-hand section. In the central area of Fig. 1*b* there are no clusters. This 'big hole' is surrounded by superclusters: the Perseus supercluster forms a wall at the near side of the hole, superclusters seen in Fig. 1*b* form walls at the left and right sides, and superclusters at redshifts $10{,}000 \le V_0 < 15{,}000$ km s^{-1} form walls at its far side.

The distribution of redshifts of galaxies in the central area of the Perseus supercluster (where there are no clusters) is given in Fig. 2*a*; Fig. 2*b* shows the distribution of redshifts of clusters of galaxies in the whole area of the Perseus supercluster, and Fig. 2*c* shows the distribution of redshifts of clusters in the remaining area outside the Perseus supercluster. There is a very strong peak in Fig. 2*a* and *b* at the redshift 5,000 km s^{-1} due to the Perseus supercluster. The distribution of redshifts at large redshift values is similar for galaxies and clusters. This suggests that galaxies situated in the central area of the Perseus supercluster form a thin stratum at the same distance as clusters form chains. The distribution of redshifts in Fig. 2*c* is completely different since it is caused by other superclusters situated at a greater distance from us.

In the direction of the Perseus supercluster there are only a few foreground and background galaxies, the vast majority of galaxies of magnitude $13.0 < \text{mag} \le 15.0$ belong to the Perseus supercluster. Thus we can use galaxy counts to estimate some numerical properties of the Perseus supercluster. The results are presented in Table 1. *N* denotes the number of Palomar Observatory Sky Survey fields, *L* the luminosity calculated by the method suggested by Jôeveer, Einasto and Tago[3], *B* the surface brightness, and %S is the per cent of spiral galaxies in the respective area. Morphological types of galaxies were taken from Nilson[8]. In the right-hand column the number of radio galaxies is given[9].

The data presented here indicate that the Perseus supercluster of galaxies is surrounded by chains of clusters of galaxies which join main density peaks—rich clusters. Main peaks have a low percentage of spiral galaxies (most galaxies are elliptical, or S0 galaxies) and contain many radio galaxies. In the central area of the supercluster the density of galaxies is small, there are no clusters here, and almost all the bright galaxies are spirals.

The total area covered by the Perseus supercluster is 5,400 Mpc^2, its mean thickness is 7 Mpc, volume 3.8×10^4 Mpc^3

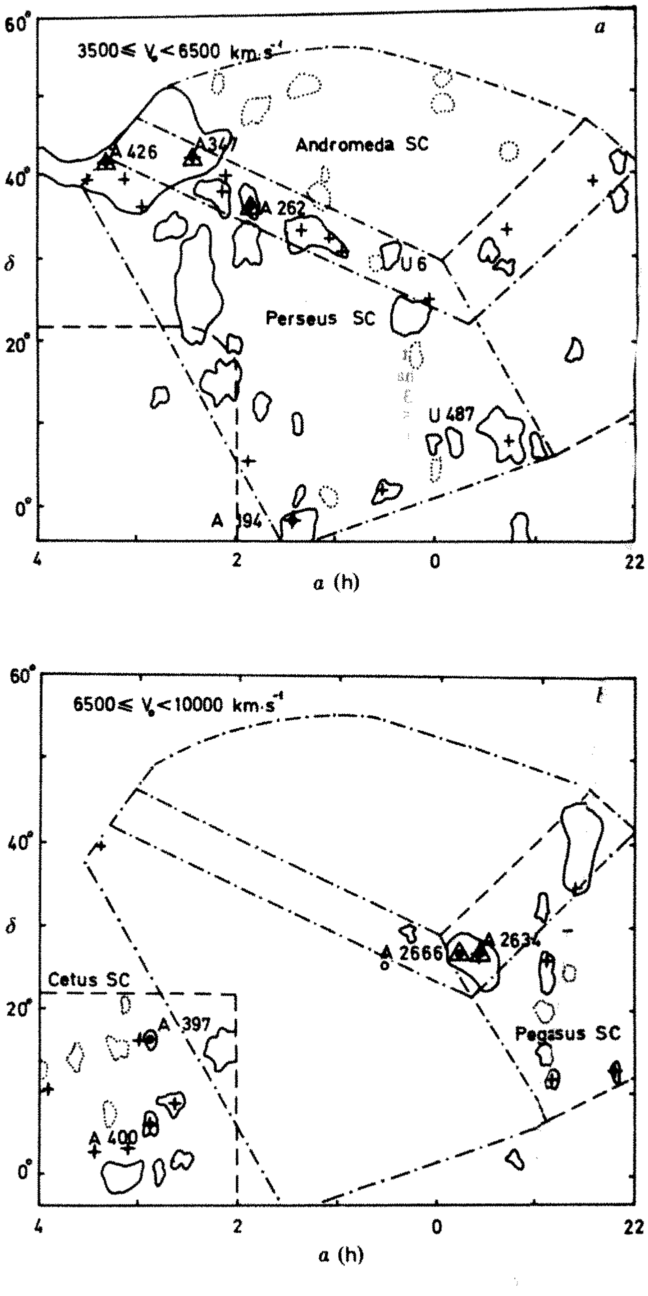

Fig. 1 The distribution of Zwicky clusters of redshifts $3{,}500 \le V_0 < 6{,}500$ km s^{-1} (*a*), and $6{,}500 \le V_0 < 10{,}000$ km s^{-1} (*b*). Zwicky clusters with measured redshifts have been drawn by solid lines, the clusters with estimated redshifts by dotted lines. Abell clusters are shown as filled circles, radio galaxies as crosses, and X-ray sources as triangles. Approximate boundaries of superclusters are shown as dashed and dotted-dashed lines.

0028–0836/80/010047—02$01.00

and mass (adopted mean mass-to-luminosity ratio 150) $2.7\times 10^{16} M_\odot$. The mean density in the supercluster is 10 times greater than the critical cosmological density[6].

Neighbouring superclusters are in contact and contain common elements. For example, the chain of clusters between clusters A426 and U6 forms the northern boundary of the Perseus supercluster and the southern boundary of the Andromeda supercluster.

In the area under study in redshift interval $3{,}500 \leq V_0 < 10{,}000$ km s^{-1} essentially all clusters are members of four superclusters (see Fig. 1). The space between superclusters (about 98% of the total volume studied[6] contains no clusters and very few bright galaxies.

A nonlinear theory of the growth of inhomogeneities suggests that the amount of matter concentrated in superclusters (initial positive density perturbations) is only a little larger than the total mass of the dark matter in big holes (initial negative density perturbations)[6]. If the density of matter associated with superclusters is $\Omega_{sc} = 0.2$ (ref. 3), then the overall mean matter density is $\Omega = 0.3$. The different large-scale spatial distribution of dark and luminous matter cannot be reconciled with pure gravitational clustering theories[10].

On the other hand, the morphology and structure of superclusters suggest that it is impossible to form superclusters in a wholly gaseous medium. In a gaseous proto-supercluster, the formation of galaxies has to begin in the central part of it, and would lead to a large cluster of galaxies rich in ellipticals in the centre of the supercluster[11]. Towards the edges the supercluster would be much thinner, and most galaxies in this region would be spirals. The observed structure is just the opposite.

Table 1 Data on the Perseus supercluster

Supercluster region	N	L ($10^{12}L_\odot$)	B ($10^9 L_\odot$ Mpc^{-2})	%S	No. of radio galaxies
Mean peaks	3	30	79	52	4
Cloud around A426	8	39	39	58	5
Perseus chain	7	60	68	68	6
Other chains	15	43	23	79	2
Central area	10	9	8	≥95	0
Total	43	181	33	68	17

This difficulty can be avoided if, following Rees[12,13], we suppose that the formation of galaxies was a two-stage process, but also that it involves much larger spatial dimensions than Rees suggested. In the first stage proto-superclusters and big holes had to form from the non-dissipative dark matter[14]. As demonstrated by numerical simulations non-dissipative matter would eventually form the observed structure with high density tips, intermediate density chains and low density walls, as long as the initial spectrum of perturbations contains large scale components[15]. In the second stage, hot gas, by cooling and settling down into the potential wells caused by dark matter, will form galaxies and clusters of galaxies[16].

The source of the Jupiter S-bursts

G. R. A. Ellis

Department of Physics, Box 252C, GPO, Hobart,
Tasmania, Australia 7001

The transient radio S-bursts from Jupiter are strongly correlated with the orbital position of the satellite Io for all wave frequencies between 8 MHz and 30 MHz, and with system III longitude above about 15 MHz. The observations are most easily explained if the electrons generating the S-bursts are confined to the planetary magnetic flux tube intersecting Io (the IFT)[1]. The primary source of the electron energy is thought to be the electromotive force (EMF) generated by the relative motion of Io across the Jupiter magnetic field, the S-bursts being the result of convective instabilities in the consequent current flow in the IFT. The electrons are assumed to emit coherent electromagnetic radiation in the Doppler cyclotron mode as they travel up the IFT after being accelerated near its feet in the Jupiter ionosphere to energies of a few keV (refs 2–4).

Simple calculations using the observed rate of change of wave frequency with time for the S-bursts ($df/dt \sim -10$ to -20 MHz s^{-1}) give 3–12 keV for the electron energy, and observations over a long period have always yielded electron energies in this range[5]. The narrow bandwidth of individual bursts ($\Delta f \sim 10$ kHz)[6] implies that their velocity spread is very small ($\Delta v/v \sim 10^{-3}$), so that the acceleration mechanism must be fairly stable and almost monoenergetic. At the same time, the magnetic field intensity in the IFT will vary as Jupiter rotates under Io owing to the non-centred location of the Jupiter

0028–0836/80/010043—03$01.00

magnetic dipole[7]. Some variation in the dynamical properties of the electrons correlated with the longitude of Io, and consequently in the properties of the S-bursts, might hence be expected.

The S-bursts were observed between 1972 and 1979 in the frequency range 2.5–17 MHz with the 650×650 m Llanherne telescope, in the frequency 17–29 MHz with a 60×60 m array, and at 24–35 MHz using a new 85×170 m array of 4,096 dipoles. RF signals were recorded on video tape for analysis with a 256-channel spectrum analyser with frequency resolution 10 kHz and time resolution 600 μs. Examples of S-burst spectra at 9, 16, 22 and 32 MHz are shown in Fig. 1. The observed distribution of df/dt with Io longitude for all the bursts observed near 12 and 15 MHz is shown in Fig. 2. Each point gives the mean value and standard deviation of df/dt during each 5-min daily observation period. Although df/dt varied between -6 and $-15\,\mathrm{MHz\,s^{-1}}$ during the period of the observations, the variation on any particular occasion was much less, with the ratio of standard deviation to the mean being typically 0.1. That is, all the bursts, of the order of a thousand, observed in 5 min on a particular day had similar frequency–time slopes but varied considerably from day to day. In Fig. 3, the observations of df/dt at various wave frequencies between 5.5 and 35 MHz are shown alternatively as a function of frequency for two regions of system III (1965) sub-Io longitude L with $180^\circ < L < 260^\circ$ and $320^\circ < L < 040^\circ$, chosen for high and low values of the magnetic field B_0 at the foot of the IFT.

If it is assumed that for emission at a particular wave frequency, taken to be the cyclotron frequency, the electrons are

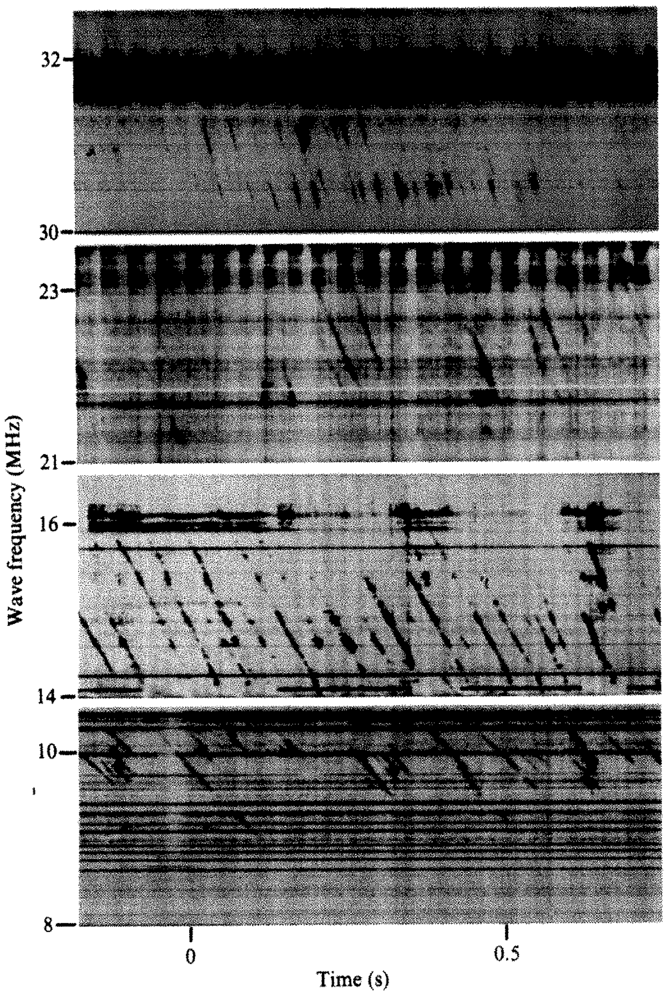

Fig. 1 Dynamic spectra of S-bursts near wave frequencies of 9, 15, 22 and 32 MHz showing their increase in frequency–time slope with frequency.

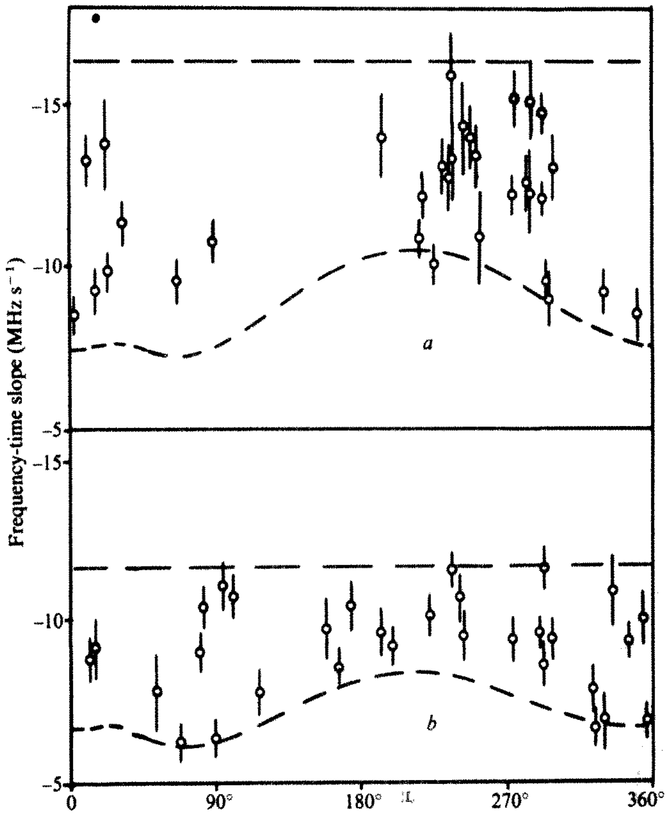

Fig. 2 Observed variation of the df/dt of S-bursts with system III longitude of Io. *a*, Wave frequency 15 MHz. *b*, Wave frequency 12 MHz. In each section the upper and lower dashed lines show the limits expected for df/dt with electron energy 3 keV and initial pitch angles 0 and $\pi/2$ respectively.

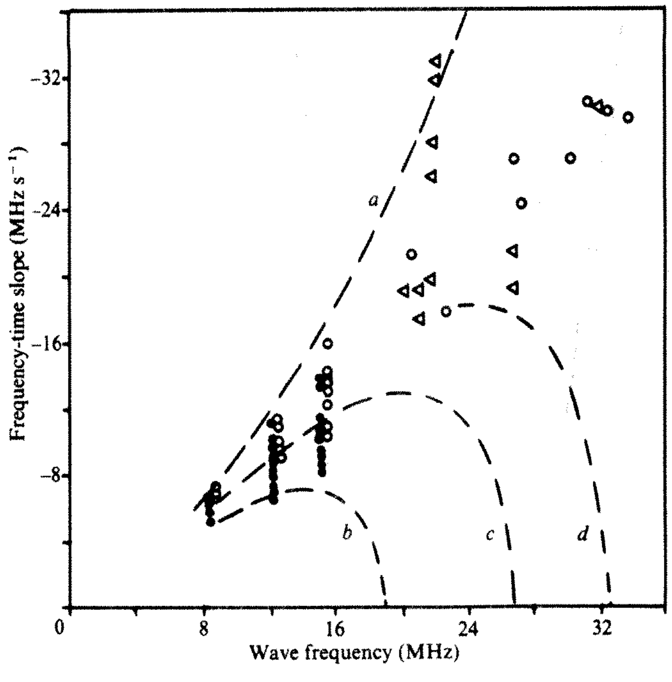

Fig. 3 Observed variation of df/dt with wave frequency from 8.5 MHz to 34 MHz. ●, Present observations, $320^\circ < L < 040^\circ$; ◁, observations reported by Desch, Flagg and May[3], $180^\circ < L < 260^\circ$; ○, present observations $180^\circ < L < 260^\circ$. The dashed lines (*a*) and (*b*) show the calculated limits of df/dt for $320^\circ < L < 040^\circ$, and (*a*) and (*c*) for $180^\circ < L < 260^\circ$. The line (*d*) shows the lower limit of df/dt expected for northern hemisphere sources only ($180^\circ < L < 260^\circ$). Electron energy, 3 keV.

all accelerated in the ionosphere to the same energy, then their longitudinal velocity at the point of S-burst emission will depend only on their initial pitch angle ϕ_0 and on B_0. That is,

$$\frac{\mathrm{d}f}{\mathrm{d}t} = -KV_{\parallel} = -KV\left(1-\frac{B}{B_0}\sin^2\phi_0\right)^{1/2}$$

where K is constant and B is magnetic field at emission point. The maximum and minimum values of $\mathrm{d}f/\mathrm{d}t$, obtained by taking $\phi_0 = 0$ and $\pi/2$, will vary with wave frequency $f(\propto B)$ and with B_0 and hence Io longitude. Figure 2 shows how the limits of $\mathrm{d}f/\mathrm{d}t$ calculated in this way vary with longitude for wave frequencies 12 MHz and 15 MHz. In Fig. 3, the same limits are shown as a function of wave frequency for the two restricted longitude regions specified earlier. Both northern and southern hemisphere values of B_0 were used for wave frequencies below 17 MHz since polarisation observations have shown that in this frequency range S-bursts may have either right-hand or left-hand polarisation[9] and may presumably originate in either hemisphere. Above 17 MHz, northern hemisphere sources were assumed.

It can be seen that all the observed values of $\mathrm{d}f/\mathrm{d}t$ fit reasonably well between limits calculated using an electron energy of 3 keV whether they are plotted against Io longitude or wave frequency. That is, with this model only a single value of electron energy with a range of initial pitch angles from 0 to $\pi/2$ is needed to account for the observed wide variation of $\mathrm{d}f/\mathrm{d}t$. The observations suggest that the electron acceleration is stable over long periods, a result which might be expected from the properties of the Io unipolar inductor[4].

This investigation was supported financially by the Australian Research Grants Committee.

Changes in the optical light curve of the Crab pulsar between 1970 and 1977

D. H. P. Jones*, F. G. Smith* & J. E. Nelson†

* Royal Greenwich Observatory, Herstmonceux Castle, Hailsham, East Sussex, UK
† Lawrence Berkeley Laboratory, Berkeley, California 94720

The pulsed optical radiation from the Crab pulsar has a characteristic and well determined profile. As the pulsar is comparatively young, the slope of this profile may be expected to change appreciably within only a few years. Our observations over an interval of 7 yr show that any such changes are surprisingly small, amounting to <1% of the peak pulse intensity.

The two profiles of the pulsed optical radiation from the Crab pulsar were obtained as follows, in sufficiently similar circumstances to allow us to search for small differences. The first observations by Nelson *et al.*[1] were made at the Lick Observatory between 15 May 1969 and 3 May 1970 using the 0.9-m Crossley reflector. Figure 1 shows a composite of the data which were collected in 25-μs intervals but shown here in 250-μs intervals—in groups of 10 bins. The data cover 72% (23.8 ms) of the cycle. The second observation was made by Smith *et al.*[2] on 26 January 1977 with the 3.9-m Anglo-Australian telescope, using an FW 130 photomultiplier with S20 response. These latter data were collected in 20-μs intervals.

The spectral responses of the two sets of observations were similar, and although no special precautions were taken to avoid sensitivity to polarisation effects, we do not consider that these could seriously affect our results. Because of the similarity of the pulse profile at different wavelengths[3] any difference in spectral response would have to be enormous to affect the results.

After allowing for the lengthening of the period by 1 part in 350, the light curves are remarkably similar. Bearing in mind that the intensity zeros and the relative phases of the two curves are unknown, we decided to fit the main peaks as closely as possible and look for any remaining differences. We first adopted a time in the Smith data corresponding to the first interval in the Nelson data. For each Nelson bin the corresponding point in the time base of the Smith curve was found by multiplying the bin number by

$$\frac{25}{20}\times\frac{0.033\,200\,3858}{0.033\,106\,1538}$$

that is, by the product of the ratio of bin sizes and the ratio of the periods[4]. The Smith count corresponding to each Nelson bin was then found by four-point lagrangian interpolation between the four Smith bins closest to the Nelson bin. It can easily be shown that, in the mean, this interpolation reduces the effective dispersion in the Smith observations by a factor 0.77. The Smith curve was then regressed on to the Nelson curve over ±6 ms centred on the main pulse. The whole procedure was repeated for a series of time-offsets between the two light curves in search of the minimum r.m.s. fit. The differences between the two complete light curves after the best fit had been obtained on the main peak are shown in Fig. 2. The data in Figs 1 and 2 are plotted in bins 250 μs wide, as we find that the differences are too small to show clearly in 25-μs bins. The scatter of points in Fig. 2 is somewhat wider than would be expected from statistics alone.

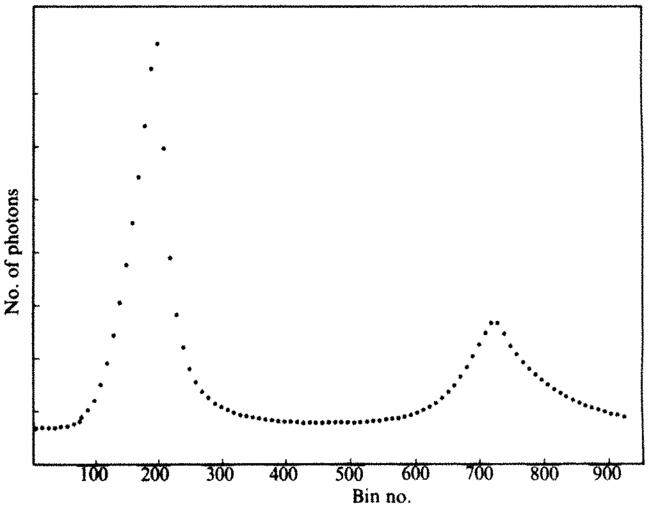

Fig. 1 Nelson *et al.*[1] light curves of the Crab Nebula pulsar. The original 25-μs bins have been averaged in groups of 10.

The two main pulse profiles evidently have a very similar shape. There are, however, two outstanding points on the steepest part of the falling slope 0.4 ms after the peak (bins 211–220 and bins 221–230). Both these show a 1% discrepancy from the intensity at that part of the curve, which is well above the statistical uncertainty. Figure 3 shows the data from the individual 25-μs bins in this region: the smoothness of the curve indicates that the difference may be real, representing a slower rate of fall in the later light curve.

0028-0836/80/010050—02$01.00

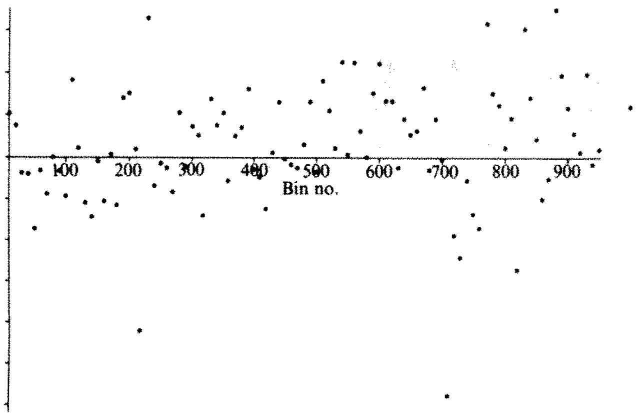

Fig. 2 The difference between the Smith *et al.*[2] curve and the 1970 curve. The ordinates have been averaged over 10 bins.

Apart from this small effect the shape of the main pulse has not changed significantly; the other differences between bins 0–300 are scattered fairly randomly about zero. No significant improvement in the two discrepant bins can be made without seriously worsening the fit elsewhere in the main pulse.

Using this best fit, three other differences can be seen in the rest of the light curve as follows: (1) base level changes: the low levels before the main pulse and the interpulse cannot both be fitted by our procedure. As the intensity is least before the main pulse[2,5], we interpret the change in terms of a constant level at this point; the result is then an increase in the level between the main pulse and the interpulse. The increase is 0.15±0.05 (s.e.)% of the peak intensity above minimum, appearing between bins 500 and 700.

(2) Relative intensity of pulses: the low values between bins 710 and 760 represent a decrease of interpulse intensity of 0.91±0.25 (s.e.)%.

(3) Spacing of pulses: the low values are not uniformly distributed around the peak of the interpulse. The interpretation of this is uncertain, as there is an irregular spread of comparatively large difference values in the region of the interpulse. A better fit for the interpulse is obtained if the spacing between main pulse and interpulse is increased by 15 μs, but it is doubtful whether this is significant. Any relative movement of the pulses cannot be greater than ~25 μs, corresponding to about 0.25° of pulsar rotation phase.

An interval of 7 yr in the life of the Crab pulsar, which is <1,000 yr old, might be expected to produce appreciable changes in the light curve. We find that the only significant changes amount to <1% of the peak intensity: they appear as a small change in the steep fall-off from the main peak, a change in the relative levels of the baseline before and after the main peak, and a decrease in the interpulse intensity relative to the main peak.

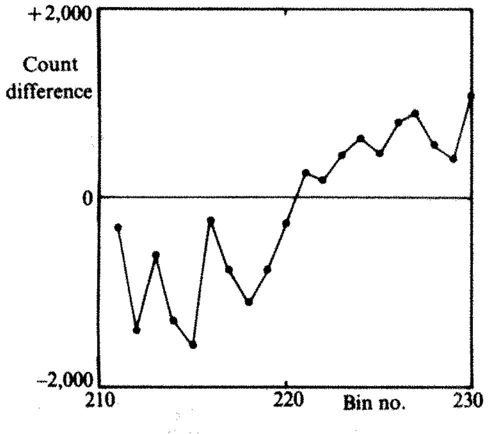

Fig. 3 Differences for 25-μs bin numbers 210–230, showing a change in the falling portion of the main pulse.

We thank Dr K. F. Hartley for helpful conversations.

The frictional anisotropy of diamond

Y. Enomoto* & D. Tabor

Physics and Chemistry of Solids, Cavendish Laboratory, Madingley Road, Cambridge, UK

If a diamond stylus is slid over a flat diamond surface in air the friction may depend significantly on the direction of sliding. The most marked effect is on the {100} faces. Along the ⟨100⟩ direction the friction is high (coefficient of friction $\mu \simeq 0.15$) while along the ⟨110⟩ direction it is low ($\mu \simeq 0.07$). This has been variously attributed to surface roughness (Coulomb friction) or to processes involving surface adhesion. (Some of these processes and related ideas are discussed in ref. 1.) We describe here some recent experiments which show that frictional anisotropy occurs only when the contact pressure exceeds a critical value. In these conditions cathodoluminescence studies of the diamond flat indicate that the frictional anisotropy is largely due to surface and sub-surface damage produced in preferred crystallographic directions by the sliding process itself. However, the results do not, as yet, provide a detailed account of the mechanism of energy dissipation.

The experiments were carried out with a very simple apparatus and involved the sliding of diamond styli over the polished (001) surface of Type I and Type II diamond. The flat surface was cleaned in air with solvents so that it was covered with oxygen and possibly other adsorbed contaminants. The styli were hemispherical sliders, of radius of curvature 18, 80 and 140 μm. The normal load could be varied from 4.9 mN (0.5 g) to 19.6 N (2,000 g) and the sliding speed was 0.2 mm s^{-1}.

The Type I diamond was polished to within 1° of a (001) plane. Polishing lines, parallel to the ⟨100⟩ direction, were visible in the optical microscope and about 1 μm apart. The Type II diamond was several degrees off the (001) plane and the polishing lines were somewhat finer. Both diamonds showed characteristic frictional anisotropy the lowest friction being along the ⟨110⟩ directions and the highest along the ⟨100⟩ directions. With the Type I diamond the frictional anisotropy was not quite symmetrical, the friction in the [010] direction being higher than in the [100]. The reasons for this will be discussed in a later, more detailed publication. With Type II diamond the frictional anisotropy was symmetrical as shown in Fig. 1. It is seen that at a load of 0.2 N (20 g) the coefficient of friction in the ⟨100⟩ directions is about 0.12 and about 0.07 in the ⟨100⟩ directions. This is not a Coulomb type of behaviour where the friction is attributed to the climbing of one surface over asperities on the other, for in such a situation the coefficient of friction is determined solely by the surface topography and is independent of the load. In contrast, in the present experiments, if the load is reduced to 0.05 N (5 g) the anisotropy disappears. This suggests that the frictional anisotropy is associated with damage produced in the flat diamond surface when the contact pressure exceeds some critical value discussed below.

This was confirmed by experiments carried out on the polished (001) surface of a Type II diamond using a stylus of radius $R = 140$ μm and loads ranging from about 4.9 mN (0.5 g)

0028–0836/80/010051–02$01.00

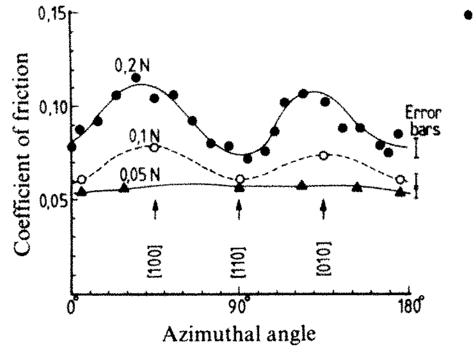

Fig. 1 Coefficient of friction μ of a diamond stylus (radius of curvature 18 μm) sliding over the (001) face of a Type II diamond. At a load of 0.2 N (20 g) the friction along the [100] direction is nearly twice the friction along the [110] direction. The frictional anisotropy is not due to a Coulomb type of friction since if the load is reduced to 0.05 N (5 g) the anisotropy disappears. Similar effects were also observed on the Type I diamond.

to 19.6 N (2,000 g). At low loads the friction ($\mu \simeq 0.07$ to 0.08) was essentially the same in the [100] and [110] directions and did not increase appreciably with load. However, in the [100] direction there was a sudden rise in friction when the load exceeded a critical value W_c: for example, at a load of 11.8 N (1,200 g) μ reached a value of 0.14. The tracks formed in this direction of sliding were examined by cathodoluminescence which reveals surface and subsurface damage. Figure 2 shows that as the damage increases, with increasing load, the friction increases. (Note that a load $W = 6.9$ N where there is a slight diminution in the amount of damage the friction shows a small drop).

A study was also made of the critical load W_c at which a marked rise in friction in the [100] direction occurred as a function of the radius of curvature R of the slider. Our experiments showed that W_c was closely proportional to R^2. If we assumed that this transition is associated with the generation of appreciable subsurface damage we may apply the principles of fracture mechanics. Frank and Lawn's[2] work on the growth of cracks in brittle solids shows that for static contact W_c should be proportional to R (Auerbach's law). On the other hand Lawn[3] has shown that in sliding contact for $\mu > 0.02$ W_c should be proportional to R^2. Our results therefore qualitatively agree with Lawn's theory and quantitatively agree if it is assumed that there are initial cracks in the surface of the order of 0.5 μm deep. The proportionality between W_c and R^2 implies that for elastic (hertzian) contact, the friction transition occurs when the mean contact pressure reaches a critical value: in our experiments this has a value of order 2,000 kg mm^{-2}.

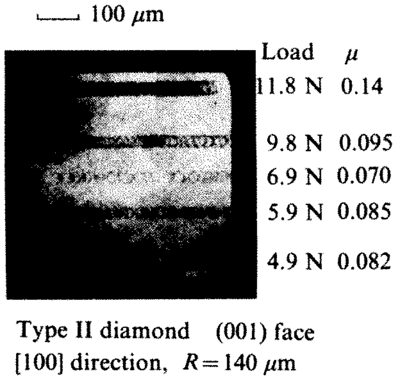

Fig. 2 Cathodoluminescence observed on the (001) face of a Type II diamond after a single to-and-fro traversal with a diamond stylus of radius $R = 140$ μm. The corresponding loads and coefficients of friction μ are indicated. There is a marked increase in subsurface damage and in μ at a load of 11.8 N (1,200 g). Scale bar, 100 μm.

We conclude that the frictional anisotropy is, to a large extent, due to surface and subsurface damage produced in preferred crystallographic directions by the sliding process itself. It is possible that some plastic grooving occurs in the friction track though the pressure of 2,000 kg mm^{-2} seems too small for this. On the other hand some microplastic deformation may be involved and contribute to the energy dissipation but the major factor apparently involves subsurface cracking which is generated when the contact pressure exceeds some critical value. This is consistent with our observations that with softer styli such as steel or even tungsten carbide frictional anisotropy is not observed over an extremely wide load range. It is also consistent with the practical observation that in the polishing of diamond with diamond powder the polishing rate is very much higher in the directions of high friction presumably because of the increased ease of producing cracks in and beneath the surface. Although these results explain most of the relevant phenomena they do not yet provide a detailed account of the way in which the energy is dissipated.

We thank de Beers and Dr M. Seal for loan of the diamond surfaces, Drs M. Chaudhri and J. Hagan for helpful discussions, and the Japanese Science and Technology Agency for a visiting research fellowship to Y.E.

Observations on internal structures of chrome alum dehydration nuclei

A. K. Galwey & R. Reed

Queen's University of Belfast, Belfast, UK

G. G. T. Guarini

Istituto di Chimica Fisica, Università di Firenze, via G. Capponi, 9, 50121, Firenze, Italy

Decomposition reactions of many solids proceed by nucleation and growth processes[1], so that the kinetic expressions used[2] and the interpretation of rate data[3] are based on quantitative consideration of the progressive changes in geometry of advancing reactant/product interfaces. Conclusions from such kinetic analyses are often confirmed by optical microscopic observations. We describe here a method whereby information may be obtained, in favourable systems, about the three-dimensional shapes of nuclei and the disposition of product particles in the wake of interface advance. For the reaction described below, the dehydration of $KCr(SO_4)_2 \cdot 12H_2O$, it is concluded that product shrinkage results in crack development through which water is evolved and crystallographic factors exert little control on the directions of interface advance during growth of the approximately hemispherical nuclei.

Most previous microscopic studies of solid state decompositions have been restricted to measurements of the numbers, distributions, sizes and shapes of nuclei within the two-dimensional plane that constitutes the crystal boundary surface. Such information is often an incomplete representation of the nuclei which may be three-dimensional assemblages of large numbers of small product particles. A new technique is described here whereby, in suitable systems, information can be obtained on

0028–0836/80/010052—03$01.00

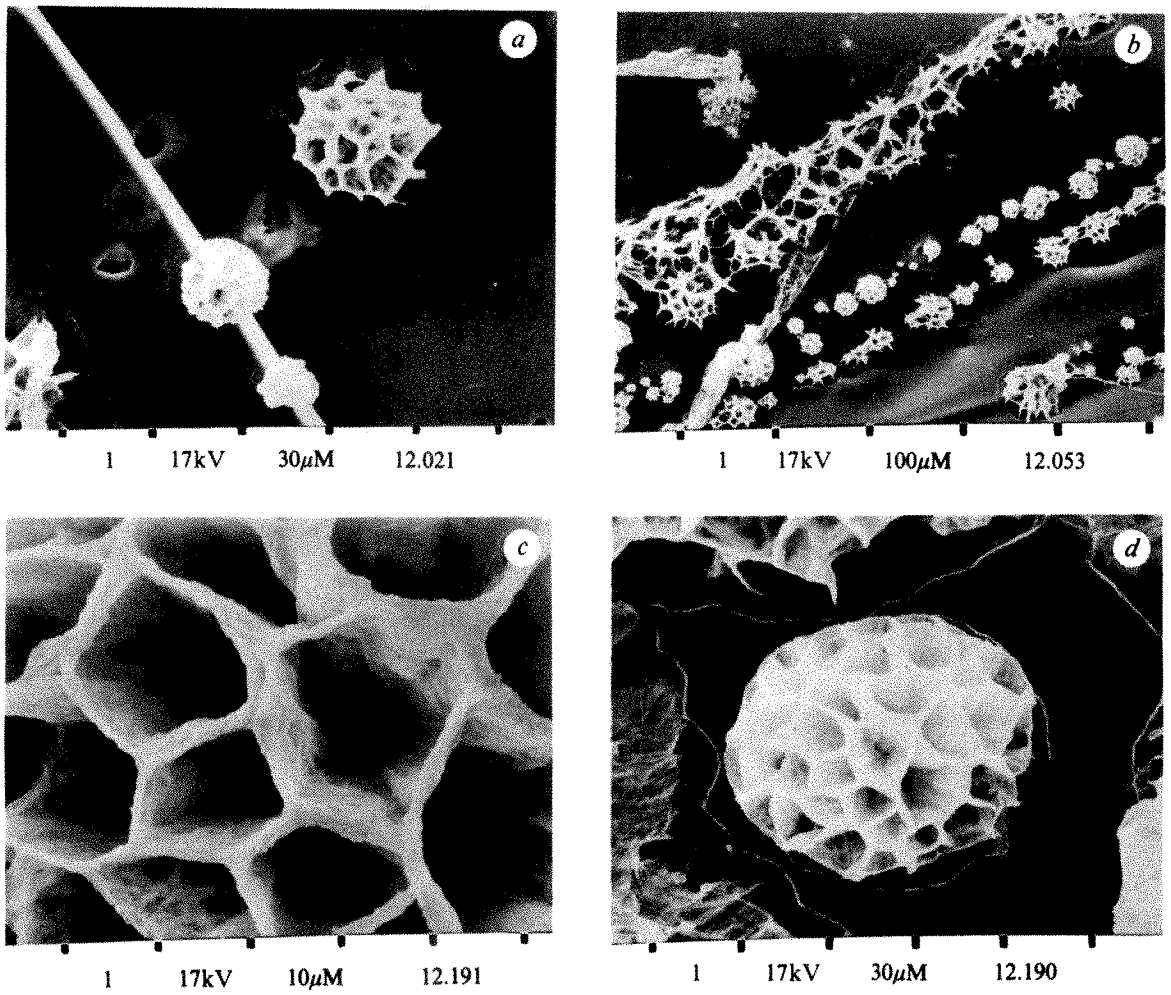

Fig. 1 Scanning electron micrographs of replicas of nuclei developed on cleavage surfaces of chrome alum, partially dehydrated in vacuum, prepared by techniques described in the text. Magnification as shown by scale on photographs. *c* Is an area of *d* more highly magnified.

the texture of the product phase, including particle sizes and any topotactic relationship with the reactant. Such evidence is particularly valuable in the formulation of mechanisms of bond and lattice rearrangement steps within the restricted zone that is regarded as constituting the active reaction interface. A knowledge of crack dimensions may permit estimation of the impedance offered to volatile product escape during reversible reactions. Present mechanisms of interface processes are usually inferred from indirect evidence such as Arrhenius parameters[1].

Figure 1 gives evidence of a regular internal crack development in the characteristic nuclei evolved during the vacuum dehydration of chrome alum ($KCr(SO_4)_2 \cdot 12H_2O \rightarrow KCr(SO_4)_2 \cdot 6H_2O + 6H_2O$; this reaction was previously studied by Garner *et al.*[4]). These are scanning electron micrographs of replicas of the nuclei, which are apparently 'seen' from a viewpoint inside the crystal. The solid replication material fills the voids within the product assemblage that constitutes the nucleus. These photographs were obtained as follows. Large (~5 mm edge) solution-grown chrome alum crystals were cleaved by a sharp blow with a knife edge and acceptable planar surfaces were dehydrated 10–30 min in vacuum ($\sim 10^{-4}$ torr) at ~300 K. The development of nuclei was confirmed by optical microscopic examination and, with minimum exposure to the atmosphere, the crystal was withdrawn from the vacuum and a drop of 2% solution of polyvinyl formal solution in dry chloroform carefully placed only on the surface of interest. After solvent evaporation and hardening of the replica (>24 h), the alum crystal was removed by dissolution in distilled water, the replica washed, dried and coated with gold–palladium before examination in the Stereoscan S180. (Alum crystals are not sufficiently stable to be directly examined in the microscope.)

Figure 1 shows representative features of typical nuclei on surfaces present after partial dehydration of cleavage surfaces of chrome alum. Figure 1*a* includes a typical nucleus having a divergent distribution of laminar cracks between product assemblages of approximately hexagonal section. At the crystal boundary plane it is possible to identify the approximately circular outline of the nucleus, locally curving outwards in the vicinity of advancing cracks, that is seen by optical examination of the crystal surface[1,4]. The oblique line is a surface step or crack, at which two nuclei have been preferentially generated, though along much of this zone and at other sites of imperfection reaction has not, as yet, been initiated. Figure 1*b* shows that there are strongly preferred directions of alignment of nuclei. Nuclei in the upper aligned band have overlapped with interlinking of volatile product escape channels. The crack systems in the lower two parallel lines of nuclei have started interpenetration but overlap is, as yet, less extensive. The crack systems characteristic of a developed individual nucleus are shown at two magnifications in Fig. 1*c* and *d*.

The development of strain during dehydration[5] is believed to result in the generation of this internal regular hexagonal disposition of cracks within nuclei, which is somewhat similar to that found in columnar basalt[6] where it has also been ascribed to shrinkage. Crystallographic factors are of little significance in controlling the direction of interface advance during growth of hemispherical nuclei in this alum.

We suggest that examination of the internal structures of nuclei, as revealed by this replication technique, provides a new approach to the elucidation of the mechanisms of solid state reactions. Evidence from the structures of dehydration nuclei developed in $KCr(SO_4)_2 \cdot 12H_2O$ supports earlier suggestions[5] that stress is an important factor in controlling product formation: a more detailed consideration of this and related reactions will be published elsewhere.

Palaeointensity and thermoluminescence measurements on Cretan kilns from 1300 to 2000 BC

Yannis Liritzis & Ruth Thomas

Departments of Physics and Geophysics, University of Edinburgh, Mayfield Road, Edinburgh, UK

The strength of the geomagnetic field in Crete during Minoan times has been determined using kiln wall samples from three Minoan palaces, Faistos, Aghia Triada and Kato Zakros, from the Minoan village at Stylos Hania and a Roman kiln at Kalo Horio. The samples have been dated by thermoluminescence measurements providing absolute dates for the construction of a palaeointensity curve. Without the thermoluminescence dates it would have been necessary to use the archaeologists' estimates of the kiln ages, one of which is shown here to be in error by 500 yr.

Kiln material was used because: (1) pottery was not readily available; (2) it was hoped that both palaeointensity and palaeodirection results could be obtained; and (3) the last firing events which were related to the destruction of the Minoan palaces could be dated by thermoluminescence measurements.

The samples, from the kiln floor, walls and heat channels, consist of a fired calcareous mud, varying in appearance from the extremes of a well fired vesicular slag (Aghia Triada and site (1) Faistos) to orange, porous, friable, less well-fired, samples with a fine mud matrix containing fragments of shells, rocks and pottery (site 1 of Kato Zakros, Stylos Hania and site 3 of Faistos); the remaining samples (Kalo Horio and site 1 of Faistos) contain a mixture of both types. Kato Zakros (2) is a brick fragment and Kato Zakros (3), a tile fragment.

The palaces sampled were of middle and late Minoan age. The earliest palace site sampled was Faistos. Kiln FS (3) belongs to the first palatial period (~2000–1700 BC) which ended when the palace was destroyed by earthquakes in about 1730 BC (ref. 1). The palace was subsequently rebuilt but in about 1500 BC it was destroyed by earthquakes or, according to some authors, by the effects of a volcanic eruption of Santorini (refs 2–5). Kiln FS (1) belongs to this second palatial period. The palace of Aghia Triada was built to replace the second palace at Faistos and probably lasted to 1400 BC (ref. 6).

The palace at Kato Zakros is thought to date from 1700 to 1400 BC. Platon (personal communication) believes that it was not rebuilt or inhabited after the catastrophic earthquake which occurred between 1450 and 1400 BC. The kiln at Stylos Hania is believed to be of late Minoan age[7] (~1300 BC); no pottery was found in the kiln but the nearby village is of that age. Kalo Horio, a Roman kiln was believed to date from ~50 BC.

Table 1 Thermoluminescence ages (yr BP)

Site	Age of sample	Estimated % error	Average site age	Estimated % error
Stylos Hania	3,882	6	3,828	4
	3,840	6		
	3,763	7		
Faistos (1)	3,466	6	3,466	6
Faistos (3)	3,806	5	3,784	4
	3,762	6		
Aghia Triada	3,545	6	3,508	4
	3,472	5		
Kato Zakros	3,370*	5	3,303	2
	3,199*	5		
	3,139*	6		
	3,289	5		
	3,519	5		
Kalo Horio	2,126	7	1,960	5
	1,795	7		

* These samples are tiles, all other samples are from kilns.

The thermoluminescence (TL) method used was the quartz inclusion technique described by Fleming[8]. TL dates can only be produced from well-fired materials so the number of dates produced was limited because of vitrification or weathering of the samples. Sample preparation and the determination of the total archaeological dose is described elsewhere[9]. The crystal sensitivity change due to heating to 500°C varied between 5 and 40%. The final total dose error was that derived from the 'dose plateau' tests, the average total doses from two or three peaks only being taken when there was good agreement between them. The β dose rates were measured in two ways, using thermoluminescent dosimetry and also using an α counting and potassium content method. The evaluation of environmental γ radiation was made on site by a portable NaI (T1) scintillometer. Results are presented in Table 1.

One disadvantage of using kiln material in palaeointensity work is that it was not originally selected by a potter and so is more inhomogeneous and complex mineralogically than pottery. Assessment of the mineralogical state of kiln wall material is complicated by the possibility that it has been repeatedly fired and cooled in various gaseous environments.

Attempts were made to determine the palaeointensities by two methods, that described by Shaw[10] and a modified Thellier method[11]. Alteration of one sort or another occurred in all samples used in Shaw's method. For most of the samples < 10% of the NRM remained after demagnetisation at the peak a.c. field of 900 Oe. The ARM2 versus ARM1 gradients were generally <1, except for samples from Aghia Triada, in many cases they had several linear portions of differing gradients.

Table 2 Results using Shaw's method

Site	No. of results	Range of uncorrected palaeointensities (Oe)	Range of corrected palaeointensities (Oe)	Mean and error of palaeointensities (Oe)
Aghia Triada	3	0.369–0.497	0.560–0.590	0.580 ± 0.034
Stylos Hania	5	0.572–0.422	0.365–0.479	0.423 ± 0.035
Faistos (1)	3	0.259–0.786	0.249–0.519	?
Faistos (3)	4	0.776–0.330	0.395–0.333	0.351 ± 0.037
Kato Zakros (1)	5	0.499–0.791	0.474–0.557	0.542 ± 0.058
Kato Zakros (2)	1	ARM and TRM plots nonlinear		
Kato Zakros (3)	3	0.485–0.788	0.512–0.560	0.540 ± 0.048
Kalo Horio	7	0.581–0.887	0.416–0.645	0.505 ± 0.066

0028-0836/80/010054—02\$01.00

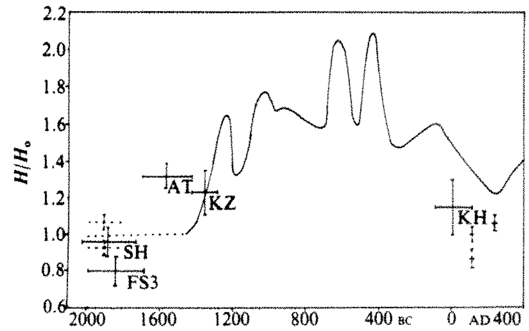

Fig. 1 The change in the ratio of the ancient geomagnetic field intensity H to the present day value, H_0 (0.44 Oe) in Crete. Each point represents several palaeointensity determinations on kiln wall material from one site. The errors are the combined errors from all determinations. The curve produced by Walton[13] is shown for comparison. The Cretan points are labelled, AT, Aghia Triada; KZ, Kato Zakros; SH, Stylos Hania; FS3, Faistos site 3; KH, Kalo Horio. Walton's points which lie away from the smoothed curve are shown by dotted lines.

The TRM versus NRM graphs often showed similar features to the ARM2 versus ARM1 graphs, and where this was the case the correction suggested by Kono[12] was applied to portions of the graph with more than six points. The scatter of results was greatly reduced and for most sites the results were self consistent (Table 2). This method does not always yield reliable results[12] so it was checked using Coe's modified version of Thelliers' method[11]. Alteration of the samples during heating was again a problem and most sites showed a wide scatter of results. The only sites for which useable results were obtained, Kalo Horio (0.506±0.110 Oe) and Kato Zakros 1 (0.484± 0.082 Oe), back up the results obtained using Shaw's method with Kono's correction.

The thermoluminescence results agree with the archaeologists' preferred chronology for the major sites. The result obtained for the less well known site of Stylos Hania suggests that it is older than was previously thought. The thermoluminescence results reinforce the suggested absolute chronology of the Minoan period but cannot rival the detail of relative chronologies deduced by the archaeologists.

The palaeointensity results in Table 2 are compared with those of Walton in Fig. 1. The age error bars on the palaeointensity curve are naturally larger than those of Walton's curve for which the relative ages of the samples are well known. It is unlikely that so precise a curve as Walton's can be extended further back in time, either using archaeological dating or absolute dating which is not yet capable of yielding the necessary precision.

Crete and Athens are ~3° latitude apart; differences in geomagnetic field intensity in the two areas are therefore to be expected. The present value for this difference is 0.01 Oe which is smaller than the errors on the palaeointensity determinations. The maximum difference in geomagnetic field intensity, at present, for sites located at the latitudes of Crete and Athens is 0.03 Oe, so it is to be expected that the palaeointensity results for Crete and Athens will agree within experimental error. This is the case for Stylos Hania and Kato Zakros. The Kalo Horio datum falls at a time where Walton seems to have ignored some data points when constructing his palaeointensity curve. If the Kalo Horio result is to be compatible with Walton data then it is necessary to postulate a fairly rapid change in the geomagnetic field strength.

The palaeointensity results reinforce the thermoluminescence date obtained for Stylos Hania, a palaeointensity of 0.42 Oe being unlikely for a sample aged 1250 BC.

We thank the Ministry of Civilisation and Science, in Athens, for permission to collect the samples, also Professor K. M. Creer and Dr H. McKerrell for helpful discussions, and Professors Platon and Davaras for archaeological advice. R.T. is in receipt of a studentship from the NERC. Y. L. is grateful for financial assistance from the National Hellenic Research Foundation and the Royal Society and The Russell Trust.

First measurements of gas phase sulphuric acid in the stratosphere

F. Arnold & R. Fabian

Max-Planck-Institut für Kernphysik, 6900 Heidelberg, FRG

Sulphuric acid is thought to be the most important nucleating agent in the stratosphere and thus has a key role in the formation of the stratospheric aerosol layer ('Junge layer')[1,2]. As the latter at least temporarily influences the Earth's radiation budget and thereby the Earth's climate[3–5], sulphuric acid is a very important stratospheric trace gas. The formation of stratospheric sulphuric acid is considered to proceed via a not yet fully determined photoreaction chain, starting from SO_2 (ref. 6). Sulphur dioxide, in turn, is thought to result from COS and possibly also from CS_2 being transported from the troposphere into the stratosphere[7]. Direct SO_2 injection is also possible. We report here the first measurement of gas phase sulphuric acid abundances in the stratosphere. Our method relies on a recent composition measurement of stratospheric negative ions which revealed the presence of species containing sulphuric acid molecules attached to HSO_4^- core ions[8,9]. Studies of relevant negative ion reactions at the NOAA-Aeronomy Laboratory[10] have confirmed the identifications and reactions of the observed ions, giving a firm basis for determination of stratospheric H_2SO_4 abundances from negative ion composition measurements.

The first composition measurement of stratospheric negative ions showing the major species and their fractional abundances are given in Table 1. The experiment was performed at an altitude of 36.5 km over southwestern France on 10 November 1977. A reaction scheme including the major ions (Fig. 1) suggests that the new cores of the $HSO_4^-(H_2SO_4)_c(HNO_3)_d$ ions are formed by H_2SO_4 reactions (reactions (1) and (4) involving $NO_3^-HNO_3$ and $NO_3^-(HNO_3)_2$. Subsequent H_2SO_4-switching reactions lead to a replacement of HNO_3 ligands by H_2SO_4. While the rate constants of the reactions (1) and (4), have been measured in the laboratory ($k_1 = 8.6 \times 10^{-10}$ cm^3 s^{-1}; $k_4 = 4 \times 10^{-10}$ cm^3 s^{-1})[10], those of the switching-processes have not yet been measured but may safely be assumed to range around 10^{-9} cm^3 s^{-1} with an uncertainty of a factor of ±2. Recombination processes of negative ions with positive ions which are not included in Fig. 1 probably all have rate constants α around 10^{-7} cm^3 s^{-1} at 36.5 km (ref. 11).

Considering the above rate constants the unknown sulphuric acid number density $n(H_2SO_4)$ can be derived from the measured negative ion composition and the measured total positive ion number density n_+ as follows: according to Fig. 1 $NO_3^-(HNO_3)_2$, the most abundant member of the $NO_3^-(HNO_3)_b$ family, is converted via reaction (4) to $HSO_4^-(HNO_3)_2$ which, in

Table 1 Mass numbers, tentative identifications and fractional abundances of the major negative ions observed at 36.5 km altitude

Mass (AMU)	Ion	Abundance (%)
125±2	$NO_3^-HNO_3$	2.6
161±2	$HSO_4^-HNO_3$	5.3
188±2	$NO_3^-(HNO_3)_2$	65.6
197±3	$HSO_4^-H_2SO_4$	6.6
224±3	$HSO_4^-(HNO_3)_2$	14.2
260±3	$HSO_4^-H_2SO_4HNO_3$	3.1
294±3	$HSO_4^-(H_2SO_4)_2$	2.6

turn, is preferably converted to $HSO_4^-H_2SO_4HNO_3$ (reaction(8)) and ultimately to $HSO_4^-(H_2SO_4)_2$ (reaction (12)). Neglecting the thermal decomposition reactions (7), (11) and (13) the steady state continuity equation for the total number density n_S of the product ions $HSO_4^-(HNO_3)_2$, $HSO_4^-H_2SO_4HNO_3$ and $HSO_4^-(H_2SO_4)_2$ becomes

$$(NO_3^-(HNO_3)_2)k_4 n(H_2SO_4) = n_S \alpha n_+ \qquad (1)$$

taking a measured n_+ of 2×10^3 cm^{-3} (ref. 9) which is consistent with a galactic cosmic ray ionisation source and the above α the sulphuric acid number density can be derived from the negative ion abundances (Table 1) using equation (1). The resulting $n(H_2SO_4)$ value is 1.6×10^5 cm^{-3} with an estimated uncertainty of a factor of ±3. Here, typical errors of factors of ±2, ±2, ±1.5 and ±1.5 were considered for k_4, α, n_+ and the negative ion abundance ratio $n_S/n(NO_3^-(HNO_3)_2$. According to Table 1 the neglect of reactions (7), (11) and (13) may have led to an underestimate of $n(H_2SO_4)$ by a factor of 1.4 at the most.

Continuity equations for ions formed from $HSO_4^-(HNO_3)_2$ and $HSO_4^-H_2SO_4HNO_3$ can also be used to derive $n(H_2SO_4)$. However, the rate constants of the switching reactions (8) and (12) have not yet been measured, assuming these to be 10^{-9} cm^3 s^{-1} $n(H_2SO_4)$ values of 8.3×10^4 cm^{-3} and 1.7×10^5 cm^{-3} are obtained having uncertainties which are again a factor of ±3.

If it is assumed that ≈50% of the $HSO_4^-H_2SO_4$ ions were formed via reaction (11) rather than via reaction (5) as suggested by the high observed ratio $n(HSO_4^-H_2SO_4)/n(HSO_4^-HNO_3)$, the former $n(H_2SO_4)$ value of 8.3×10^4 cm^{-3} had to be corrected upwards by a factor of about 1.57 which yields 1.3×10^5 cm^{-3}. Thus the three derived $n(H_2SO_4)$ values are in excellent agreement within the errors quoted. Therefore a sulphuric acid concentration of 1.7×10^5 cm^{-3} with an uncertainty of a factor of ±3 is taken to be representative of our data. The corresponding H_2SO_4 volume mixing ratio is 0.0017 p.p.b.V.

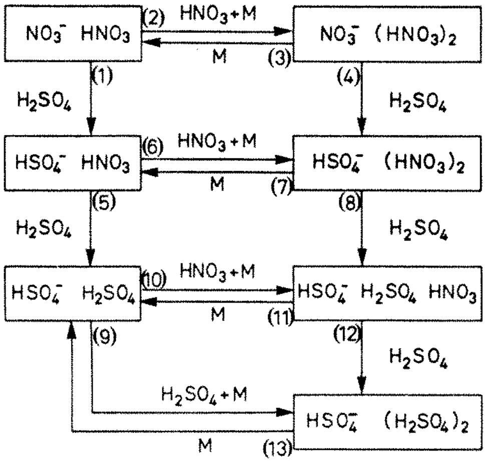

Fig. 1 Reaction scheme including the major negative ions observed. Neutral reaction partners are indicated besides the arrows. M denotes a collision partner.

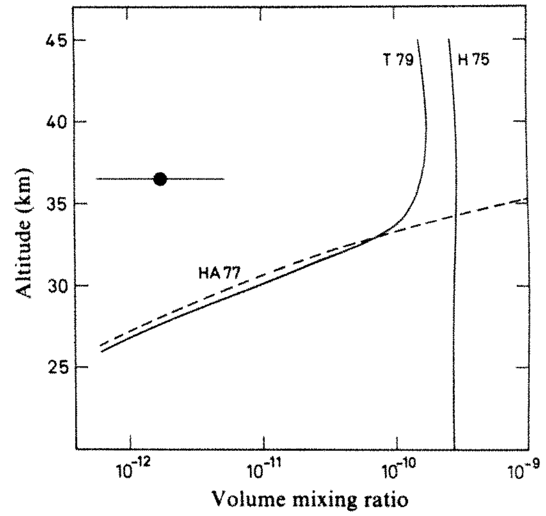

Fig. 2 Volume mixing ratios for gas phase sulphuric acid. ●, The measured value. Profile HA 77 is deduced from vapour pressure data given by Hamill *et al.*[12]. Profile H 75 is given by the photochemical diffusive model of Harker[13]. Profile T 79 is given by the photochemical diffusive model of Turco *et al.*[6] which includes aerosol processes.

This experimental value is compared here with predictions of current models for stratospheric sulphur compounds. Major H_2SO_4 sinks considered are nucleation and photolysis[6]. At heights where the atmospheric temperature is sufficiently low to allow for H_2SO_4 supersaturation, nucleation should be by far the most efficient sink for gas phase H_2SO_4. Then the lifetime of an H_2SO_4 molecule in the gas phase is determined mainly by the surface area density of the aerosol which, in turn, depends on the concentration and size distribution of the aerosol particles. In these conditions, a lower limit to the sulphuric acid abundance may be estimated from vapour pressure considerations assuming sulphuric acid to nucleate as a binary system (H_2SO_4–H_2O) which leads to the H_2SO_4 volume mixing ratio profile shown in Fig. 2 (ref. 12). The profile corresponds to a mean temperature profile for mid-latitude spring–autumn conditions as given by the US standard atmosphere (1966) and to a constant water vapour volume mixing ratio of 3.5 p.p.m.V.

An upper limit to the sulphuric acid abundance may be estimated from photochemical–diffusive models neglecting H_2SO_4–aerosol processes. As an example, a profile deduced from Harker's model[13] (case 1) is also shown in Fig. 2. When compared with the profile based on vapour pressure considerations, this gives higher values at heights below ~34 km, implying that H_2SO_4 nucleation in the binary system occurs below this height for the temperature profile used. Considering the lower temperature measured during our balloon experiment at 36.5 km (227 K compared with a value of 239 K as used by Hamill *et al.*[12] the H_2SO_4 vapour pressure and thus the H_2SO_4 abundance should have been considerably lower than that shown in Fig. 2. According to the data given in Table 1 of Hamill *et al.*[12], the difference may be of the order of a factor of 20.

An H_2SO_4 profile given by a recent comprehensive model which considers photochemistry, vertical transport and aerosol processes of sulphur compounds[6] is also shown in Fig. 2. This profile which is based on the same temperatures as the profile of Hamill *et al.*[12] is similar, as would be expected from a combination of the limiting profiles H 75 and HA 77 (see Fig. 2).

When compared with our experimental sulphuric acid abundance also given in Fig. 2, the model values are much too high. Considering, however, a lower H_2SO_4 vapour pressure associated with the lower temperature measured during our balloon experiment the expected H_2SO_4 volume mixing ratio at 36.5 km may have been low as about 0.15 p.p.b.V. which is much closer to the experimental value but still far too high.

Therefore, current models apparently fail to describe the abundance of stratospheric gas phase sulphuric acid. Possible causes such as an overestimate of the H_2SO_4 production or an underestimate of the H_2SO_4 loss will now be briefly investigated. The most severe uncertainties of the model computations seem to be associated with (1) poorly known natural fluctuations of the vertical transport of COS strongly affecting the COS abundance and thus the H_2SO_4 production around 36 km; (2) unknown photoabsorption coefficients for H_2SO_4 which were simply assumed to be the same as those of HCl (ref. 6); (3) considerable uncertainties of H_2SO_4 vapour pressure computations[14,15]. Considering a discrepancy between experimental and model H_2SO_4 abundances of about a factor of 100 it seems that each of the above uncertainties may be sufficient to account for the disrepancy. Other processes which were not included in the models may be responsible. One is H_2SO_4 nucleation in the hypothetical three-component system (H_2SO_4–HNO_3–H_2O) which is suspected to have a much lower H_2SO_4 vapour pressure than the two-compoent system (H_2SO_4–H_2O)[16]. Whether or not H_2SO_4 nucleation can account for the low sulphuric acid abundance observed, may be judged from a comparison of H_2SO_4 lifetimes in the gas phase. The lifetime for nucleation t_N is of the order of 3×10^5 at 36.5 km if a typical nuclei concentration of $10\,cm^{-3}$ and a typical nuclei size of 0.04 μm (ref. 17) are considered. For comparison, the lifetime t which can be derived from the experimental sulphuric acid concentration using an H_2SO_4 production rate of about $0.6\,cm^{-3}\,s^{-1}$ at 36.5 km (deduced from the model of Turco *et al.*[6]) is about 3×10^5 s. The agreement of t and t_N suggests that at least as far as time constants are concerned the low H_2SO_4 abundance observed is consistent with an efficient removal of gas phase H_2SO_4 by nucleation. The critical question is whether H_2SO_4 was at all supersaturated and thus able to nucleate.

An alternative sink for gas-phase H_2SO_4 may be reactions with negative ions followed by the formation of stable ion pairs which ultimately become incorporated into aerosol particles[18]. The H_2SO_4 lifetime for this process may be as low as about 5×10^5 at 36.5 km which is close to the inferred t.

The cause of the discrepancy between experimental and theoretical abundances of gas phase sulphuric acid in the stratosphere can not be identified with certainty. Further *in situ* measurements of H_2SO_4 abundances need to be extended in height and they should be carried out in conditions of different stratospheric temperatures. Particularly in summer, when the mean temperature around 36 km may be as high as about 252 K in middle latitudes, the vapour pressure of H_2SO_4 should be higher than during our present experiment (227 K) by 2 or 3 orders of magnitude. If such an increase was observed H_2SO_4 nucleation could be identified as the cause in question.

We thank E. Ferguson and F. Fehsenfeld for data on sulphuric acid ion reactions, and E. Ferguson for helpful discussions. Part of the project was funded by the Bundesministerium für Forschung und Technologie through GSU.

Stratospheric observation of far IR pure rotational lines of hydroxyl

D. J. W. Kendall

The hydroxyl radical, OH, has a key role in many atmospheric and ionospheric processes and has been detected in molecular clouds in space. The well-known near IR vibration–rotation bands of this molecule, named after their discoverer, Meinel, were first identified in atmospheric observations[1] while much of the impetus for precise microwave data has come from the identification of radiation in this wavelength range from OH in space[2]. However, although increasingly precise measurements have now been reported from the UV[3] through the IR[4] to the microwave spectral regions[5], the far IR pure rotational line spectrum has been virtually ignored, and no observations of this relatively simple spectrum have been reported between 5 and 500 cm^{-1}. Here we present measurements of spectra between 30 and 110 cm^{-1} and deduce stratospheric OH column densities from the observed spectral lines.

We have recalculated[6] the expected pure rotational line positions for all vibrational levels up to and including $v = 9$ for the ground electronic $^2\pi$ state and have derived values for the integrated intensity ($cm^{-2}\,atm^{-1}$) for these lines in the ground electronic and vibrational state at a temperature of 220 K, corresponding to a mean stratospheric temperature. This study showed that the integrated intensity values were very large and suggested that pure rotational lines would be detectable in far IR emission spectra taken in the stratosphere from a balloon platform.

This prediction is important as the amount of hydroxyl in the stratosphere has become an important, even vital, parameter in the current debate on the possible modification of the ozone layer by halocarbons, and measurements of this radical are urgently needed for inclusion in models of ozone behaviour[7]. Only one group has reported direct measurements of OH in the stratosphere[8], and values obtained by a balloon-borne *in situ* sampling technique, in conjunction with a ground-based resonance fluorescence measurement[9] have shown that the stratospheric OH concentration apparently exhibits large daytime variations. Recent theoretical calculations have shown that while the greatest concentration of OH occurs in the mesosphere at 80 km at night, this peak in the OH density profile moves to the upper stratosphere at 40 km during the daytime[10,11].

The predicted line strengths for pure rotational lines of OH led to the careful examination of emission spectra of the stratosphere taken during a balloon flight series in 1976 from Yorkton, Saskatchewan, Canada (51.3° N, 102.3° W). On one of these flights on 15–16 August, 1979, a simple rapid-scanning Michelson interferometer[12] measured a series of high resolution (0.05 cm^{-1}) spectra between 30 and 110 cm^{-1} of the stratosphere, at an angle of 84.2°, from an altitude of 24.5 km during the evening and sunset periods. An average of 15 of these spectra has been obtained, selected sections of which are presented in the upper parts of Fig. 1*a–c*. The low altitude and high zenith angle conditions combined to produce very strong H_2O emissions and to enhance weak O_3 lines. In these spectral regions, the predicted positions for the Λ-type doublet OH lines are indicated. Figure 1*c* shows a predicted H_2O and O_3 spectrum, produced from the AFGL line listing[13]. The present

0028–0836/80/010057—02$01.00

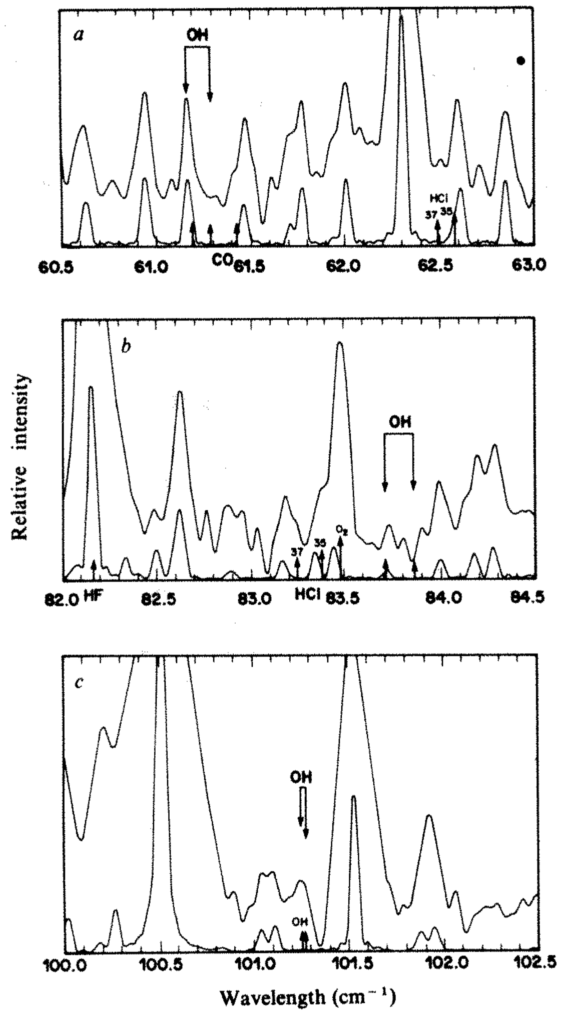

Fig. 1 *a–c*, Sections of the stratospheric far IR emission spectrum, observed at a mean altitude of 24.5 km at a zenith angle of 84.2°. These sections are the sum of 15 unapodised spectra computed at a resolution of 0.05 cm^{-1}. An equivalent synthetic spectrum for H_2O and O_3 to a resolution of 0.05 cm^{-1} is shown below each section.

spectra are somewhat better than those previously reported from a different flight[6] in having higher resolution and better signal-to-noise ratio in the spectral data. As can be seen from Fig. 1, the OH line positions for the ground electronic and vibrational state are in spectral regions which are relatively free of other lines, and, even though some blending with weak O_3 lines occurs, and other small features in the spectrum are at present unassigned, a tentative identification of pure rotational OH emissions can be made. The lines at 61.29 cm^{-1} (with an observed feature at 61.30 cm^{-1}), at 83.85 cm^{-1} (observed feature at 83.90 cm^{-1}) and the combined and strong feature at 101.26 cm^{-1} can be used along with the predicted line strengths[6] to yield an average column density of OH of $8(\pm 3)\times 10^{13}$ molecules cm^{-2}. Assumption of a constant mixing ratio above the altitude of 24.5 km yields a value of about 0.1 parts per 10^9 by volume for this mixing ratio, a value which is in reasonable agreement with the values obtained by Burnett[9].

Thus, even this rather tentative identification is encouraging in indicating that the technique may prove particularly valuable for monitoring this important constituent in the stratosphere, at least during the daytime. Emissions from the higher layers during night-time hours would perhaps make interpretation of the data difficult, although such results might be of interest in their own right for other scientific studies. Higher resolution and sensitivity in the instrumentation during future observations should improve the identification of these pure rotational OH lines, and angular scanning of the instrument across the atmospheric limb to high zenith angles should allow a profile of OH density to be obtained, a parameter which would be of great value in ozone layer modelling. There is also an urgent need for laboratory measurements to verify the position and integrated intensity values for these pure rotational far IR transitions.

We thank the Atmospheric Environment Service of Canada and the NRC of Canada for financial support.

Methyl chloride in the stratosphere

There is much current interest in the chemistry of the stratosphere and the possible impact of chlorine compounds on the Earth's ozone layer. Profiles of anthropogenic compounds such as $CFCl_3$ and CF_2Cl_2, which are emitted from aerosol spray cans, have already been measured in the stratosphere[1]. They confirm that substantial photolysis of these compounds is occurring and thereby releasing chlorine atoms which can catalyse ozone removal. The only natural chlorine containing compound which is likely to enter the stratosphere at significant concentrations is methyl chloride. It is therefore important that its profile be measured and compared with a computed profile to ascertain the likely impact on the ozone layer of naturally occurring chlorine. We report here measurements of the methyl chloride concentration profile up to an altitude of 32 km. The concentration falls off with altitude due to reaction with hydroxyl radicals and it confirms that chlorine of anthropogenic origin is now predominant in the stratosphere.

Lovelock[2] first reported the presence of methyl chloride in the atmosphere at the 1–2 p.p.b. level (1 p.p.b. = 1 part in 10^9 by volume) and showed that its concentrations were highest in air whose origins were oceanic rather than continental. Measurements in seawater confirmed that the ocean could indeed be a significant source in addition to that produced by the smouldering combustion of vegetation. Subsequently studies have provided considerable information on the tropospheric distribution of methyl chloride. Singh *et al.*[3] report mean concentrations of 611 ± 84 p.p.t. (1 p.p.t. = 1 part in 10^{12} by volume) and 615 ± 103 p.p.t. in the Northern and Southern Hemispheres, respectively. They find evidence for a large, natural oceanic source and estimate a global source strength of 3×10^{12} g yr^{-1}. Rasmussen *et al.*[4–6] find similar values in both hemispheres, with higher values in the atmospheric mixing layer over oceans, strongly indicating an oceanic source. Additionally, they have given

Table 1 Measurements of methyl chloride in the stratosphere during June 1978 at 44° N

Probe no.	Altitude	Latitude	MeCl (p.p.t.)	Comments
1	32.6 km	44° N	6.6 8.5	Repeat analysis
2	31.3 km	44° N	57.5	
3	28.4 km	44° N	62.3 59.4	Repeats, also 50/52 ratio taken
6	19.7 km	44° N	375	
7	17.5 km	44° N	476	50/52 ratio taken.
	0.1 km	51° N	590 651 759	Harwell ground level samples

Methyl chloride levels are given in parts per 10^{12} in air by volume. Measurements at Harwell were made on the day of analysis (20 March 1979).

some attention to Lovelock's suggestion concerning 'slash and burn' agriculture. Elevated concentrations are clearly evident in Kenya and concentrations up to 2 p.p.b. have been reported[7]. In view of the widespread nature of this agricultural practice in tropical latitudes[8], this source may be of some significance when it is appreciated that much of the transport to the stratosphere takes place through the tropical tropopause[9]. The importance of this source for the stratosphere may not necessarily be reflected in the relative source strengths (3×10^{12} g yr^{-1} for the natural oceanic[2] and 3–6 × 10^{11} g yr^{-1} from the combustion of vegetation)[10]. A measured altitude profile of methyl chloride would certainly help resolve the magnitude of the stratospheric chlorine injection and the relative contributions from the ocean and combustion sources.

To measure methyl chloride in the stratosphere we utilised a balloon probe which collected 10-l samples of air at STP at eight altitudes during the descent phase of the balloon between 32.6 and 17.5 km. The samples were taken over France at a latitude of 44° N. They were cryotrapped into reservoirs contained in the probe using liquid neon and precautions were taken to avoid contamination from the balloon assembly[1]. The air samples in the reservoirs were subsequently transferred into 600 ml stainless steel flasks fitted with metal bellows valves. The pressure in the flasks was typically 4 bar at the time of analysis. Air from the flasks was analysed for a number of components using a gas chromatograph/mass spectrometer combination (Hewlett Packard 5710 GC/VG Micromass 16F MS). Methyl chloride was separated on a 3-m OV 101 column at 20 °C and was measured by single ion monitoring at mass 50. The ratio of the signals from mass 50 to mass 52 was measured in two of the stratospheric samples and it compared well with that expected for methyl chloride. About 100 ml of air was used for each analysis and the signal-to-noise ratio was such that 5 p.p.t. could be measured with ±50% accuracy.

The results for a flight in June 1978 are given in Table 1, and the altitude profile in Fig. 1. Also shown in Table 1 are measurements made at ground level at Harwell on the day of analyses. These agree well with previous determinations of methyl chloride in the troposphere[3,6], and confirm that little or no decay had occurred in the containers between flight time and analysis. Unfortunately no data are available between 28 and 20 km because of a malfunction in the balloon probe. In consequence, data are available for only five altitudes, but these show a regular decrease with height in good agreement with our calculated profile. This calculated profile was obtained using a one-dimensional model described elsewhere[11]. This calculation utilised available rate coefficients for the $OH + CH_3Cl$ reaction[12,13], UV absorption cross sections for CH_3Cl (ref. 14) and a lower boundary concentration of 600 p.p.t. at 12 km established on the basis of aircraft measurements[4,5].

Table 2 Contributions to the stratospheric chlorine budgets from the various halocarbons

Halocarbon	Chlorine contribution p.p.b.	Comment	Refs
Methyl chloride	0.7	Natural	This work
Carbon tetrachloride	0.5	Man-made	3, 19
CCl_3F	0.4	Man-made	3, 19, 20
CCl_2F_2	0.4	Man-made	3, 20
Other organic chlorine compounds*	0.6	Man-made	21
Total	2.6		

* CH_3CCl_3, CHF_2Cl, C_2Cl_4, $CHCl_3$, CH_2Cl_2, C_2HCl_3.

The close agreement between calculation and observation is typical of the behaviour found[11] for other trace gases whose sources are widely distributed throughout the troposphere. This suggests that methyl chloride is predominantly oceanic in origin. A substantial tropical injection from 'slash and burn' agriculture would result in considerable deviation between the observed profile (at 44° N) and the calculated profile (for 30° N) in the lower stratosphere due to polewards transport by the mean circulation and large-scale eddies. In the absence of a significant additional tropical injection, published values of the tropospheric levels of halocarbons can be used to estimate the likely contribution from natural and man-made compounds to the chlorine content of the stratosphere. Table 2 shows that the chlorine from natural methyl chloride is heavily outweighed by chlorine from man-made sources.

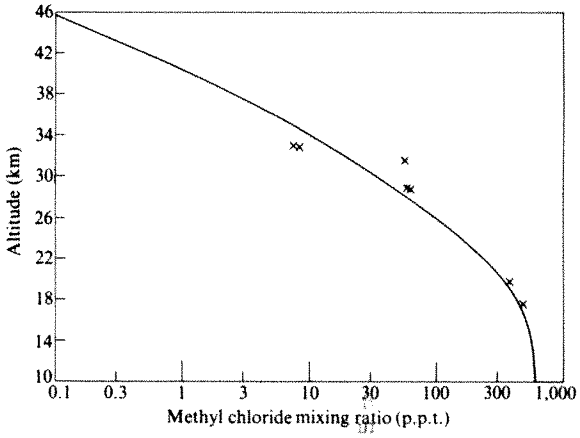

Fig. 1 Observed and calculated altitude profiles of methyl chloride. X, Measurements at 44° N during June 1978; line, calculated with 1-D model[11] using the K_z profile of Chang[22].

Finally it should be noted that the maximum amount of chlorine which can be expected from compounds presently known (2.6 p.p.b.) is substantially lower than the chlorine measured in the form of HCl and ClO in the stratosphere. Recent measurements give values of HCl up to 2 p.p.b. (refs 15, 16) and ClO between 2–8 p.p.b. (refs 17, 18) pointing to an apparent discrepancy which is beyond the scope of the present letter to discuss in detail.

The work at AERE Harwell was performed as part of an air pollution research programme sponsored by the UK Department of Environment. Balloon flights were sponsored by the German Federal Ministry of Research and Technology (grant FkW-03).

Two types of clinoenstatite in Indarch enstatite chondrite

C. A. Leitch & J. V. Smith

Department of Geophysical Sciences, University of Chicago, Chicago, Illinois 60637

Enstatite chondrites are characterised by highly reduced minerals[1,2]. Clinoenstatite and rare olivine are almost Fe-free, carbon occurs as graphite, and Fe, Ni-rich metal contains up to 4% Si. Ca, Ti, Mg and Mn, normally incorporated solely in silicates, are distributed between silicates and sulphides; Ti may also occur as a nitride. We now describe two types of clinoenstatite in the Indarch enstatite chondrite, one luminescing blue and one red. These clinoenstatites have distinct chemical compositions which indicate different redox conditions. The Indarch chondrite is an unannealed mechanical aggregate of diverse materials, and cannot have formed by simple progressive condensation of the solar nebula.

The Indarch chondrite contains four chondrule types[3]: porphyritic (most abundant), fine-grained, radiating, and barred. Although the minerals of the chondrules appear homogeneous in a petrographic microscope, a cathodoluminescence microscope revealed distinct red and blue types of clinoenstatite crystals. Complex changes of intensity of luminescence occur across some grains, but no chemical variation was found by electron microprobe analysis. Perhaps the intensity change results from crystallographic factors dependent on orientation of twinned and disordered regions. (The polymorphic type of pyroxene was not identified in the polished section but is assumed to be clinoenstatite following ref. 2). Each porphyritic chondrule contains both blue and red crystals but with a strong majority of either one or the other. Radiating chondrules contain large near-euhedral crystals of blue clinoenstatite surrounded by a radiating matrix of red clinoenstatite and other minerals (Fig. 1), perhaps resulting from devitrification. Fine-grained chondrules contain blue clinoenstatite except for a thin rim of red clinoenstatite found in one chondrule. All four types of chondrules are surrounded by a shell of fine-grained material composed of all mineral types found in the meteorite. A shell also occurs around chondrules in some ordinary chondrites[4].

Electron microprobe analyses (Table 1) were obtained with an ARL-EMX instrument. Mg, Si and Fe were determined with a solid-state detector, 15 kV, 0.1 μA beam current, 120 s live time. Synthetic $MgSiO_3$ glass was the standard for Mg and Si, and P-140 olivine for Fe. Minor elements were determined with spectrometers at 25 kV and 2 μA. Counting times for peak and background were chosen to give a precision near 30 p.p.m. (1σ) for an individual analysis; precision of mean values is lower. Standards were $Di_{85}Jd_{15}$ glass (Ca, Na, Al), $Ca_2P_2O_7$(P), Corning glass V (Ti, Cr), Corning glass W(Mn) and Corning glass X(Ni). Secondary fluorescence could contribute but is significant only for Fe analyses made on clinoenstatite lying close (<0.1 mm) to metal or troilite. Analyses deliberately made on clinoenstatite crystals distant from metal and troilite varied only about 10% in Fe whatever the colour of the clinoenstatite and the type of host chondrule, but random analyses showed some higher values of Fe. The slightly high totals (100.5–101.6) probably result from a small change of thickness of carbon coat between the standard and the unknown; such a small change would have only a trivial effect on atomic ratios.

The minor elements correlate with the luminescence colour but not with the chondrule type. Whereas the red clinoenstatites have higher concentrations of Ti, Al, Cr, Mn and Ca, the blue ones tend to have higher Na. Assignment of valence states to minor elements in pyroxenes depends on crystal-chemical theory, and the following assignments follow currently accepted practice based on ionic potentials.

For blue clinoenstatite, P was assigned to $NaMgSiPO_6$, Ti to $NaTiAlSiO_6$, Al to $NaAlSi_2O_6$ and Cr to $NaCr^{3+}Si_2O_6$. The remaining Na could not be accounted for except by assuming a corresponding amount of trivalent iron in the acmite unit $NaFe^{3+}Si_2O_6$, or the alternative of vacant sites. Based on 24 oxygen atoms per cell, 0.004–0.017 Fe^{3+} atom was needed. The remaining divalent species were coupled with Si. For a perfect analysis, there should be eight Si atoms per cell, apart from the trivial deviation caused by the insignificant amounts of P and Ti, and indeed the observed values of Si lie within experimental error of eight atoms.

For red clinoenstatites, P was assigned to $NaMgSiPO_6$, Ti to $NaTiAlSiO_6$ and the remaining Na or Ti to either $NaAlSi_2O_6$ or $MgTiAl_2O_6$. Some Al and Cr was still unused, and it was necessary to use $MgAl_2SiO_6$ and $MgCr^{3+}{}_2SiO_6$ units. Furthermore, the sum of the remaining divalent ions (assuming all Fe as Fe^{2+}) was less than the number of Si^{4+} ions. Because the blue clinoenstatites calculated closely to an MTO_3 formula, this discrepancy was not attributed to experimental error, and about one-third of the Fe was converted to the trivalent state. A similar conclusion with slightly different numbers was reached more directly by adjusting the oxygen/metal ratio to the theoretical value of 3:2 by converting some Fe to the trivalent state.

Note that our suggestion of the presence of Fe^{3+} is questionable because it depends on crystal-chemical assumptions and analytical error. Direct spectral evidence is needed to confirm or refute the suggestion. A wet chemical analysis for a pyroxene separate from the Kota-Kota enstatite chondrite[5] showed a deficiency of Si, 0.93 wt % FeO, and only 0.03% Fe_2O_3. For the present, we note that even if there is no Fe^{3+} in the Indarch clinoenstatites, the unequal content of Ti, Cr, and Mn in the red

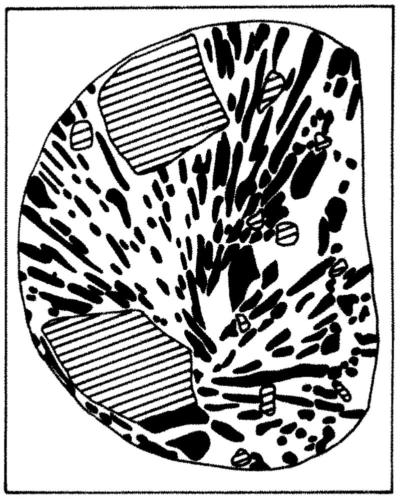

Fig. 1 Schematic representation of a fragment of a radiating chondrule. Black areas are red clinoenstatite; hatched regions are blue grains; clear areas are composed of glass or very fine-grained sulphides. The maximum width of the chondrule is 600 μm. Thin section from Field Museum collection.

and blue clinoenstatites must indicate different redox conditions if both clinoenstatites equilibrated with sulphide.

Mechanical aggregation of diverse source materials is required to explain the complex texture and bimodal chemistry of the clinoenstatite. Direct derivation from hypothetical progressive condensation of a gaseous solar nebula can be ruled out, and a complex origin is needed, perhaps involving a rapidly cooled cloud of solid particles, liquid droplets and gas undergoing aerodynamic sorting[6] coupled with settling onto the surface of a growing planetesimal. Perhaps the cloud formed from collision between two planetesimals[7]. Petrographic and mineralogical evidence is accumulating for the presence of assemblages in chemical disequilibrium in all types of unequilibrated chondrites (as reviewed in ref. 7, and emphasised in ref. 8).

Absence of a reaction zone between adjacent blue and red clinoenstatites rules out prolonged annealing of the Indarch enstatite chondrite. If the clinoenstatites really do contain some trivalent iron, they could not be in chemical equilibrium with Si-containing Fe,Ni metal, and mechanical aggregation from two distinct source regions would be implied. Indeed the clinoenstatite-bearing chondrules do not contain large fragments of metal. Tiny grains of metal, too small for routine analysis with an electron microprobe, occur in the porphyritic chondrules, but are tentatively attributed to mechanical aggregation and vapour deposition during coalescence of the red and blue clinoenstatites.

There is undoubted petrographic and chemical evidence of chemical disequilibrium in the Indarch enstatite chondrite. The implied presence of trivalent iron needs testing by spectral techniques, and detailed analyses of trace elements are needed for all minerals. Preliminary study of the Abee, Kota-Kota and Adhi-Kot enstatite chondrites has revealed both red and blue enstatites, and electron microprobe analyses are in progress.

Gravity anomalies, block-faulting and Andean-type tectonism in the Eastern Churchill Province

M. D. Thomas

Gravity and Geodynamics Division, Earth Physics Branch, Department of Energy, Mines and Resources, Ottawa, Canada K1A OY3

P. Kearey

Department of Geology, Queen's Building, University Walk, Bristol, UK

Evaluation of the tectonic evolution of Precambrian terrains may be greatly enhanced by selecting appropriate analogues from Phanerozoic examples where the geological history is better understood and where a knowledge of current geodynamic processes is sometimes available. The Churchill Structural Province in the eastern Canadian Shield apparently has a close analogue in the central Andes of Peru where the Nazca plate continues to thrust below the South American plate. We propose that this provides the basis for a tectonic framework that explains several geological features both within the Churchill Province and at the adjacent boundaries with the Superior and Nain provinces.

The Churchill Structural Province in northeastern Quebec and Labrador is characterised by a distinctive pattern of coextensive, parallel, regional gravity anomalies extending laterally 300–450 km and having widths between 45 and 100 km. These anomalies strike approximately north-northwest and parallel large-scale features, such as the boundaries of the Churchill Province with the Superior Province to the west and the Nain Province to the east, certain major lithological units (Fig. 1), and structural trends apparent from field data and air photographs[1].

The negative–positive pair of anomalies *a* and *b* (Fig. 1) have been related to structures formed by the collision of Superior and Churchill protocontinents during the Hudsonian Orogeny[2] following subduction of the Superior-bearing plate beneath the Churchill Province. The structures are consistent with a 'basement reactivation' model[3], in the context of which negative anomaly *a* was explained by downwarped Superior crust and positive anomaly *b* by topography on the Conrad discontinuity, developed during collision, within the thickened Churchill crust[2]. The same dipolar gravity signature is common to several of the structural province boundaries in the Canadian Shield[4]. The type structure of such boundaries, interpreted as sutures, consists of an older crustal block, that thickens towards the suture, in steep contact with a relatively thicker and denser, younger block, both blocks being in approximate isostatic equilibrium.

Suggested causes of gravity anomalies east of the boundary pair are topography on the Conrad discontinuity[2,5] and, in some cases, lithological variations[5]. However, there are several lines of evidence, including the extensive nature of the gravity anomalies themselves, to indicate that these regional anomalies are related to major, fault-bounded crustal blocks which are laterally extensive, of differing density and in relative isostatic equilibrium[6] (see model, Fig. 2*A*); previous interpretations[2,5]

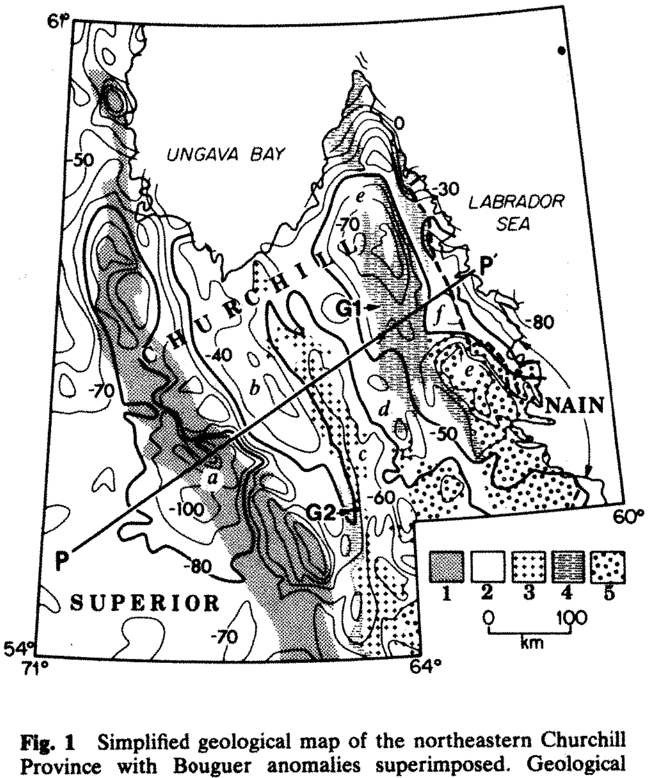

Fig. 1 Simplified geological map of the northeastern Churchill Province with Bouguer anomalies superimposed. Geological legend for Churchill Province: 1, Labrador Trough; 2, mixed gneisses and migmatites; 3, granites and granodiorites; 4, granulites; 5, anorthosites and adamellites. G1 and G2 indicate areas of granulite. The Churchill–Nain boundary is identified by bold dashed line. Bouguer anomalies are reduced to sea level using a uniform density of 2.67 g cm^{-3} and are contoured at an interval of 10 mGal. Bold contours outline anomalies (*a–f*) discussed in text. P–P′ is profile interpreted in Fig. 2*A*.

are not necessarily invalidated by this hypothesis but rather become a matter of detail. Geological evidence for all of the large-scale faults interpreted in the model is incomplete, perhaps due to the reconnaissance nature of the mapping and the considerable cover of glacial drift[7,8]. Nevertheless, a 200-km long fault zone has been identified close to the gradient separating anomalies *e* and *f* where it forms much of the eastern boundary of a large area of granulites (G1, Fig. 1). Faults have also been mapped[9,10] along 100 km of the western border of granulites (G2) which correlate with the southern part of positive anomaly *b*. Other prominent faults in the region have north and northwesterly strikes and are indicated by zones of mylonite[7,8]. Relative vertical movements of crustal blocks are indicated by the juxtaposition of high and low grade metamorphic rocks: amphibolite facies terrain to the east of the Labrador Trough underlying anomaly *b* has probably risen 10–15 km relative to lower grade terrain to the west[11]. The eastern limit of this uplifted terrain may coincide with a change in the pattern of aeromagnetic anomalies that occurs roughly along the −40 mGal contour on the east flank of gravity anomaly *b* (Fig. 3) and is considered further evidence in support of a zone of major faulting between blocks underlying anomalies *b* and *c* (Fig. 2*A*).

The gravity model of the Churchill crust (Fig. 2*A*) is comparable in morphology and scale to a crustal model of the Andes proposed for central Peru[12] (Fig. 2*B*). Development of the latter model over the past 100 Myr has been influenced by large-scale vertical faults[12–14] parallel to the Peru–Chile trench that may result from strong coupling between the Nazca and South American plates[15]. Movement along these faults has controlled the following aspects of Andean geology: basin development, batholith emplacement, and the style of deformation of basin fill[12,14]. Basin development and batholith emplacement in the Churchill Province likewise seem to have been controlled by major faults, but any comment regarding deformational styles is precluded by a lack of detailed structural information and the high metamorphic grades. The remains of a former major sedimentary basin, the Dorset Fold Belt[16], have been identified in the region of negative gravity anomaly *e* (Fig. 1) and continue into Baffin Island. Its Andean analogue is the East Peruvian

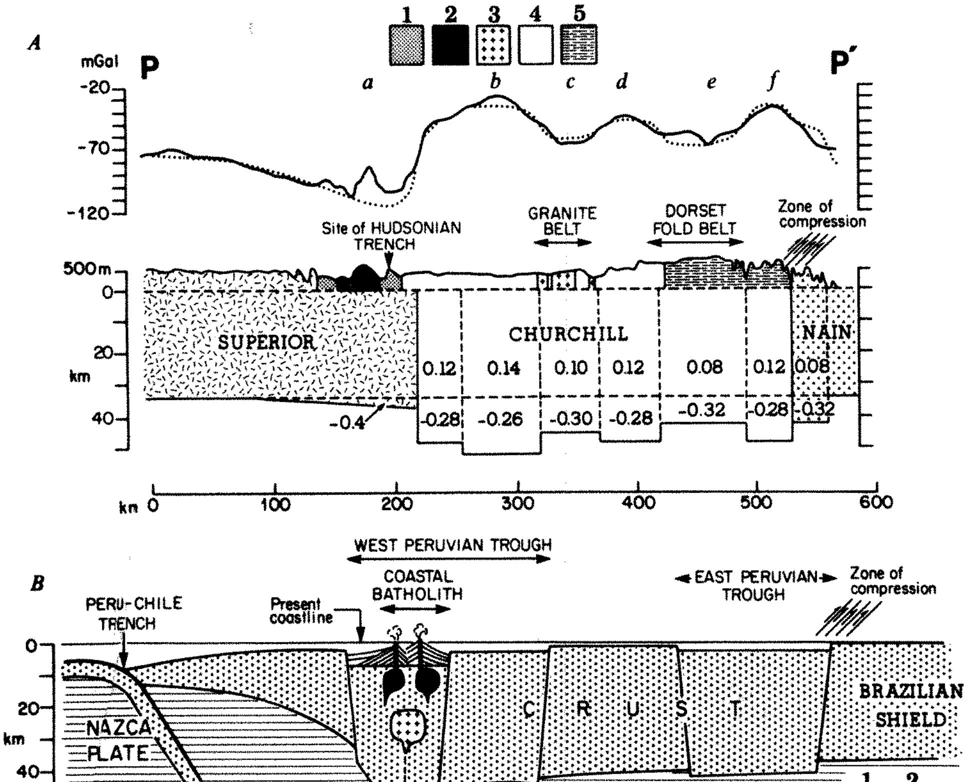

Fig. 2 *A*, Interpretation of gravity profile P–P′ with Churchill Province modelled as several blocks, each in relative isostatic equilibrium. Solid line, observed gravity; dotted line, calculated gravity. Letters *a–f* identify anomalies discussed in text. Geological legend: 1, metasediments of the Labrador Trough; 2, basic igneous rocks of the Labrador Trough; 3, granitic rocks; 4, mixed gneisses and migmatites; 5, granulites. Density contrasts in g cm^{-3}. *B*, Schematic interpretation of a crustal section across the central Andes at 100 Myr ago (after Myers[14]). Geological legend: 1, basic intrusions; 2, the rising Coastal Batholith.

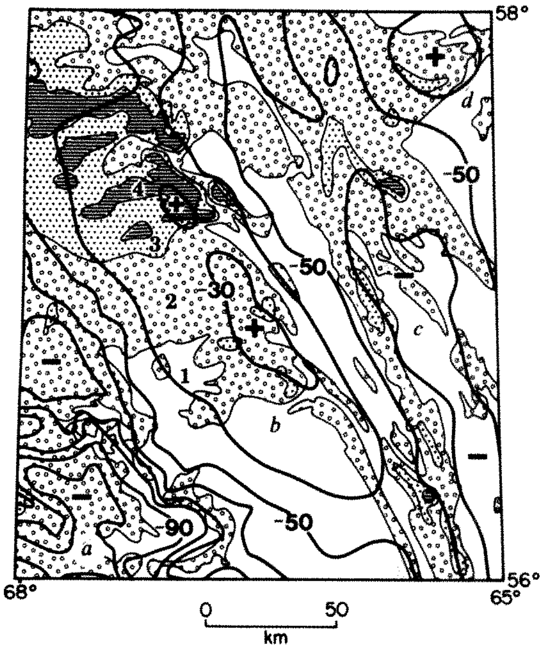

Fig. 3 Portion of Churchill Province adjoining the Labrador Trough for which there are published aeromagnetic data. Aeromagnetic anomalies are contoured at 400 nT intervals and increase in intensity from pattern 1 to pattern 4. Superimposed Bouguer anomalies are contoured at 10 mGal interval and outline parts of anomalies *a*, *b*, *c* and *d* (Fig. 1). A change in the crustal character is evidenced in the aeromagnetic anomalies approximately along the line of the −40 mGal Bouguer anomaly contour which lies along the gradient between anomalies *b* and *c*.

Trough (Fig. 2*B*). Negative gravity anomaly *c* (Fig. 1) coincides with an almost continuous belt of granitic rocks 500-km long. The restriction of granitic rocks to a narrow, linear belt suggests that they have their analogue in the Andean Coastal Batholith which may have been localised by major shear zones and was formed from plutons and sheets intruded into the same tabular belt by repeated cauldron subsidence[12]. Further, the noted absence of syn- and post-orogenic granitic intrusions within the Circum-Ungava belt[17,18] could be explained if the Churchill granite had a similar spatial relationship to the interacting Superior and Churchill plates as the coastal batholith had to the Nazca and South American plates. By this analogy, no granites would be expected within the Labrador Trough, here interpreted as the approximate site of the Hudsonian trench. Rather, granites would be expected some 230 km east of the trough; they are, in fact, centred 70–150 km from the trough (Fig. 1). The smaller distances, most probably, are a result of crustal shortening associated with collision, although the angle of subduction also may have been a contributing factor. Shortening of the Labrador Trough deposits, by thrust faulting and folding, is estimated[19] to have been at least 113 km. The Churchill basement to the east also bears evidence of shortening in the form of tightly pinched synclines, many overturned towards the Superior Province[18]. Radiometric ages (K–Ar) on the Churchill granitic rocks[7] of 1,580 Myr[20] and 1,595 Myr[21] indicate that they were intruded during the late stages of the Hudsonian Orogeny.

According to our model the Churchill–Nain boundary represents the eastern limit of crustal reactivation related to subduction of an oceanic plate, bearing the Superior Province, below an Archean protocontinent comprising what are now the Churchill Province and the North Atlantic Archean Craton[22]. Above the subducted plate, reactivation processes—manifest as the Hudsonian Orogeny—have reset the radiometric clock and transformed Archean crust to Proterozoic crust at the same time imparting to it structural characteristics which distinguish the region as the Churchill Province. The Nain Province, a segment of the now dissected North Atlantic Archean Craton, remained unaffected. Detailed mapping[23] at the Churchill–Nain boundary has revealed evidence of crustal compression in the form of west dipping thrusts and axial planes of folds attributed to the Hudsonian Orogeny. The structures at this boundary have their counterparts in the Andes where similar compressive tectonics occur in the sub-Andean ranges[24] centred some 500–700 km east of the Peru–Chile Trench. Here, the crust has been compressively deformed from the west against the Brazilian Shield along a belt that marks the eastward limit of intraplate deformation associated with subduction of the Nazca Plate[25,26] (Fig. 2*B*). There has been recent speculation that the flat geometry of the Nazca Plate, dipping at about 10°, may be responsible for the broad zone of deformation across the central and northern Peruvian Andes[15]. This raises the possibility that the Superior-bearing oceanic plate also subducted at a shallow angle.

Viewed in the light of an Andean analogue several diverse features of the eastern Canadian Shield can be related to a single Proterozoic geodynamic system involving the interaction of two converging plates. Collision tectonics seem to dominate in the region within and bordering the Labrador Trough, but further east it is likely that the geology has evolved in response to the underthrusting of a Superior-bearing oceanic plate.

Recrystallisation and electrical behaviour of glacier ice

J. M. Reynolds & J. G. Paren

British Antarctic Survey, Natural Environment Research Council,
Madingley Road, Cambridge, UK

Electrical d.c. resistivity measurements made on the George VI Ice Shelf have established the polar nature of Antarctic ice despite saturation by melt-water from surface melt-lakes. Previously it has been suggested that different impurity concentrations are responsible for the extremes in resistivity (a factor of 1,000) between temperate ice (essentially at its pressure melting point) and polar ice (well below its pressure melting point). However, the evidence suggests that impurity levels are similar despite the leaching of contaminants by free water in temperate glaciers, a process which is absent in true polar glaciers. This implies that, although impurities can significantly alter the electrical behaviour of glacier ice, there is a more fundamental mechanism at work. We suggest that this process is one of recrystallisation.

0028–0836/80/010063—02$01.00

Georesistivity measuring techniques have been applied to the sounding of ice masses many times during the last 25 years. Studies on European glaciers indicate that temperate ice has a resistivity of about 10^8 Ωm (refs 1–6). Mono- and polycrystalline ice grown slowly from pure water in the laboratory has given similar values of 2×10^6 to 5×10^8 Ωm (refs 7, 8). Experiments carried out on ice from polar regions which is well below its pressure melting point have indicated that its resistivity is three orders of magnitude smaller than that of temperate glacier ice, typically between 5×10^4 and 1.5×10^5 Ωm (refs 9–15), and that the resistivity is temperature and density dependent[10,16]. Electrical experiments undertaken in the laboratory[17,18] on cores taken from both temperate and polar glaciers have confirmed the extreme differences with respect to *in situ* measurements. Recent work has sought an explanation for this marked diversity in resistivity.

Previous *in situ* measurements have been made in the dry-snow and percolation zones of polar ice masses[1–6,12] (as defined by Müller[19]) and in the ablation zone of temperate glaciers[9–15,20]. It was with this background that a comprehensive resistivity survey was carried out on George VI Ice Shelf in the Antarctic Peninsula (71°58′ S, 67°34′ W) during January and February 1979. This particular ice shelf undergoes extensive surface melting during the summer and melt-lakes are formed which saturate the firn although the mean annual temperature for the area is −11 °C[21]. There are two basic layers in the ice shelf. At least the top 25 m of the ice shelf consists of locally accumulated snow which has been modified shortly after its deposition by free water from melt-lakes on the surface. Beneath this layer there is dense dry firn and ice from outlet glaciers flowing from the Palmer Land plateau, a cold (−20 °C)[22] dry-snow environment.

One of the aims of our study was to determine the extent to which free surface water which is subsequently frozen affects the electrical properties of ice in an area thought to be transitional percolation-soaked zone. We found that resistivities lay in the range $(5.9 \pm 1.7) \times 10^4$ Ωm, a value which is typical of cold, dry polar ice. This is an important result because it shows that the free water has affected the resistivity only indirectly. In a cold, dry region the transition from fresh snow to dense glacier ice is by a process of densification. The Ross Ice Shelf is an example of such an area and its resistivity profiles reflect a gradual increase in density with depth[13] (mean 10 m density is 0.425 Mg m^{-3}). On the George VI Ice Shelf, where the mean 10-m density is 0.832 Mg m^{-3}, our resistivity data imply that the density-depth effect is much less marked than on the Ross Ice Shelf. The water in George VI Ice Shelf melt-lakes freezes in late summer to form extensive thick ice layers of very dense ice (0.913 Mg m^{-3}) which sandwich bands of firn. The main process of densification is by percolation and refreezing and not simply by compaction. A low frequency resistivity of 10^5 Ωm was obtained for ice in a shallow lens formed from melt-water within the last 10 years. This resistivity value is comparable with those of the rest of the ice shelf. Hence, the electrical behaviour of high density ice formed on a cold glacier by compaction is very similar to that of ice formed by the percolation and freezing of melt-water. This implies that the stabilisation of the electrical behaviour of ice is completed within a few years after the ice forms even though recrystallisation continues throughout the life of the ice.

One explanation of the difference in behaviour between samples of temperate and of polar ice (and indeed, between polar ice samples of different depositional age) has been the amount of impurities (CO_2[23,24], and volcanic acids[25]) which remain in the ice after firnification. Yet soluble impurity levels in polar ice and ice in the ablation zone of temperate glaciers are similar and do not differ by orders of magnitude[23,24]. Impurity concentrations, although able to modify electrical behaviour significantly, cannot provide the basic mechanism which accounts for the difference between temperate and polar ice[26].

We wish to draw attention to the consistency of polar ice resistivities even where melt-water is present. Two potentially important mechanisms which operate in temperate glaciers and which are reduced or absent in polar ice masses are the complete removal of melt-water runoff and the extent of recrystallisation that occurs in response to stress. We now suggest that these factors may be responsible for the differences in the electrical behaviour between polar and temperate ice.

Prediction and test of the effects of interspecific competition

Göran Högstedt

Department of Animal Ecology, University of Lund,
S-223 62 Lund, Sweden

Although interspecific competition is of major importance in ecological and evolutionary theory[1], there has been no critical study of whether indirect estimates of niche overlap accurately reflect the effects of competition on fitness as indicated by reproductive output. I report here that competition from jackdaws, *Corvus monedula*, significantly reduced reproductive output of magpies, *Pica pica*, due to starvation of nestlings and a high rate of nest predation. The competition coefficient as estimated from these direct effects ($\alpha = 0.43$) was only slightly smaller than predicted by niche overlap values based on morphological similarity, habitat distribution and feeding technique ($\alpha = 0.58$), or food composition ($\alpha = 0.54$).

The study was carried out in a south Swedish grassland habitat with scattered young pine plantations, most of them containing one pair of magpies. Niche overlap was estimated in two ways. First, the percentage overlap[2] in the frequency distribution of jackdaws and magpies foraging in different habitats (areas with heath, grassland, tall herbs and pines), and using different feeding techniques (gleaning, probing and chasing) was determined. The ratio of bill sizes in the two species was also calculated. The product of all these values gave an estimate of overall niche overlap of $\alpha = 0.58$. Second, samples of food brought by the parents to their nestlings were identified to species level, except for cereals and a few unimportant categories. The percentage overlap in frequency distribution of the food of the two species yielded $\alpha = 0.54$.

If jackdaws and magpies compete for limited resources, one would expect the effects of competition on reproductive output to be closely related to these overlap values, provided the values

Table 1 Breeding results of experimental and control pairs of magpies

	Experimental group	Control group	*P* (two-tailed)
Start of laying (median date) day 1 = 1 April	20	21	NS
Clutch size	6.50 ± 0.30	6.48 ± 0.18	NS

give an accurate measure of niche overlap. The values are directly comparable to the competition coefficient because the two species have almost identical weights and, therefore, also identical consumption rates.

This prediction was tested with a 2-yr experiment. Three jackdaw nest-boxes were put up in each of a number of experimental magpie territories. The nest-boxes were occupied immediately by jackdaws. Pairs of magpies served as controls and experimental birds in alternate seasons, so that their breeding success in the two situations could be compared. Combined data from all experimental and control pairs for the two seasons are shown in Table 1, and the reproductive output of individuals in experimental and control conditions is shown in Table 2: this comparison can be made only for birds that were individually marked and survived both breeding seasons. The start of laying and the size and weight of clutch were similar for the two groups, whereas experimental pairs produced fewer young, with lower weights at fledging, than did control pairs.

The competition coefficient for the effect of jackdaws on magpie reproduction (α_{mj}) is defined by:

$$N_{\mathrm{m}} = C - \alpha_{\mathrm{mj}} \times N_{\mathrm{j}} - D$$

where N_{m} and N_{j} are equilibrium numbers (adults plus nestlings) of magpies and jackdaws respectively, C is carrying capacity and D is the impact on magpie reproduction of competitors other than the jackdaw. Assuming identical C and D for experimental and control territories, the competition coefficient may be determined from

$$\alpha_{\mathrm{mj}} = \frac{N_{\mathrm{m}}\,(\text{control}) - N_{\mathrm{m}}\,(\text{exp.})}{N_{\mathrm{j}}\,(\text{exp.}) - N_{\mathrm{j}}\,(\text{control})}$$

This coefficient can be calculated on the following assumptions. (1) The difference in the numerator amounts to 1.35 magpie nestlings (Table 1). As Fig. 1 shows, the difference in reproductive output between pairs of experimental and control magpies is established well before the end of the nestling period. Thus, equilibrium seems to be attained. (2) The time spent by foraging adult magpies and jackdaws in 25 × 25-m plots was recorded 26–30 d after hatching, during 7 h of observation in each of three experimental and two control territories. Magpie foraging areas (≧ 1% of total magpie foraging time) were of similar size in experimental and control pairs, on the average 0.96 and 1.00 ha, respectively. The total number of 'jackdaw feeding minutes' in the magpie foraging areas of experimental pairs were 411, 563 and 575 and of control pairs 24 and 50. This corresponds to an average number of 1.23 foraging jackdaws in experimental magpie territories and 0.09 in control ones. As magpies foraged during 91% of total observation time, these figures are corrected to 1.35 and 0.10, respectively. Consequently, there was a mean difference of 1.25 foraging adult jackdaws between experimental and control magpie territories. (3) The mean number of nestlings in the jackdaw nest-boxes was 2.29 (s.e. = 0.19). Thus, 1.25 adult jackdaws provided food, both for themselves and for, on average, 1.25 × 0.5 × 2.29 = 1.43 nestlings. (4) As magpies and jackdaws hatch almost simultaneously and their nestlings weigh approximately the same, the energy requirements of the nestlings of the two species are almost identical. Thus, for the denominator in the above quotient to be directly comparable to the numerator (= 1.35 magpie nestlings) the denominator should be transformed into number of jackdaw nestlings. It is estimated that energy consumption of an adult jackdaw exceeds that of a nestling by about 35 to 40% (refs 3–4). Thus the difference between the numbers of jackdaws at experimental and control magpie territories, 1.25 and 1.43 nestlings, will be equivalent to a total of 3.15 jackdaw nestlings. As a result

$$\alpha_{\mathrm{mj}} = \frac{1.35}{3.15} = 0.43$$

This competition coefficient agrees fairly well with the predictions of niche overlap, based on circumstantial evidence.

A directional index[5] $[\alpha_{\mathrm{mj}} = (\sum_{\mathrm{h}} p_{\mathrm{jh}}\, p_{\mathrm{mh}})\ (\sum_{\mathrm{h}} p_{\mathrm{mh}}{}^{2})^{-1}]$ has often been used to estimate competition coefficients. Using this index and assuming equal extraction rates for all kinds of prey and equal consumption rates for the two competitors[6], values of 1.04 (based on bill dimensions, habitat distributions and feeding techniques) and 0.69 (based on food composition) are obtained for the competitive effect of jackdaw on magpie, and 0.59 and 0.71, respectively, for the reverse effect. This method leads to high expected competition coefficients, and it may not be so useful in natural conditions[7], as also indicated by the results reported here.

The competitive effects of jackdaws foraging in magpie territories were evident in the following sequence (Tables 1 and 2 and Fig. 1). The presence of jackdaws had no effect during the earlier stages of magpie breeding, before hatching. This is probably explained by a slight difference in time of laying, the magpie being 5 d ahead of the jackdaw, and the relatively small energy demands of the birds during the early phase of breeding. There was no sign of interspecific aggression during this period. After hatching, experimental magpies lost nestlings to a markedly higher degree than did control pairs. Both starvation and nest predation (chiefly by hooded crows, *Corvus cornix*) caused these losses, and the effects of these two factors were of similar magnitude. During this period magpies became highly aggressive—101 attacks on foraging jackdaws were recorded

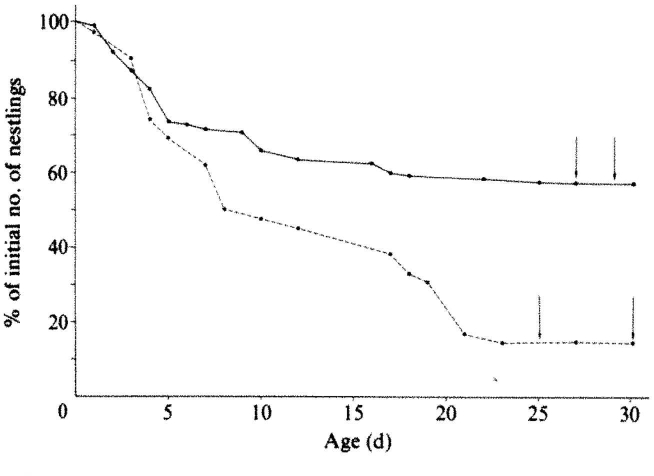

Fig. 1 Mortality of experimental (----, see text) and control (——) magpie broods. Arrows delimit periods of observation on jackdaw distribution in magpie feeding areas. In the control group there were 115 hatched young, and in the experimental group, 42.

Table 2 Breeding results of individual females in experimental and control conditions, in the same territory

during 35 h of observation. The jackdaws probably depleted available food in the magpie territories, thereby causing starvation of the magpie nestlings. Food depletion may have forced the parent magpies to forage farther from their nest than normal, thereby reducing the possibilities of defending their nest against predators. Furthermore, hungry nestlings beg for food loudly, thus increasing the risk of predator attraction.

I thank Dr T. Alerstam for valuable criticism and for improving this report, I. Rudebeck for typing the draft and Professor S. Ulfstrand for stimulating discussions and financial support (grants from the Swedish Natural Science Research Council).

Plants metabolise ethylene to ethylene glycol

Dale C. Blomstrom & Elmo M. Beyer Jr

Central Research and Development Department, Experimental
Station, E.I. du Pont de Nemours and Company, Wilmington,
Delaware 19898

Ethylene is a natural plant growth regulator often produced in sufficient quantities to alter cellular and developmental processes in a characteristic hormonal manner[1]. Almost all phases of plant development are affected, including germination, growth, flowering, dormancy, abscission, senescence and sex expression. The earlier view that ethylene is metabolically inert[2–4] has been shown to be untenable[5–7]; low but readily detectable rates of ethylene metabolism have been observed in several plant tissues. These and other studies[8–10] indicate that this metabolism does not represent a system for the removal of the ethylene but instead represents the initial biochemical events in the action of ethylene in the plant. Here we report that one of the stable end-products of this ethylene metabolism is ethylene glycol, while for the ethylene mimic propylene, it is 1,2-propanediol.

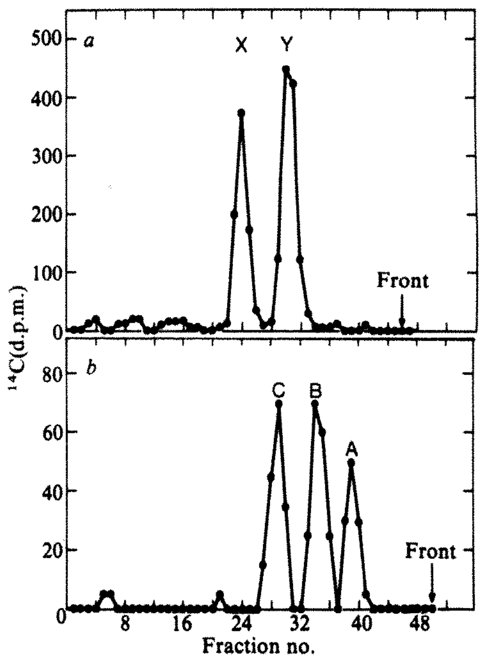

Fig. 1 Separation of neutral metabolites of *a*, ^{14}C-ethylene and *b*, ^{14}C-propylene by paper chromatography with butanol:acetic acid:water 3:3:2.

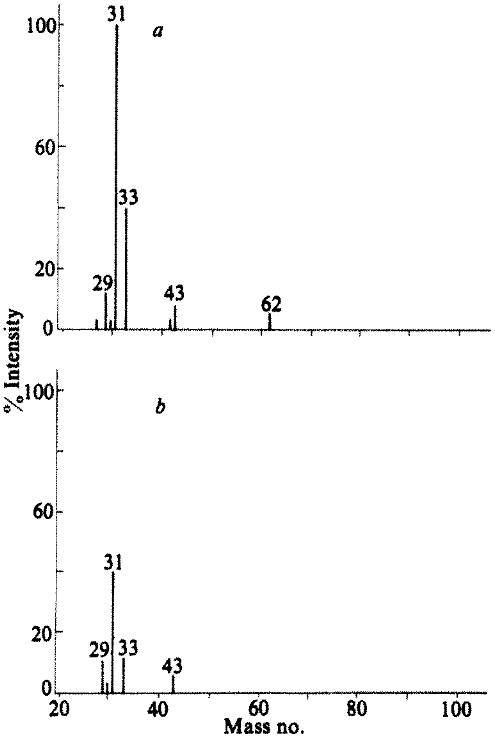

Fig. 2 Identification of ethylene metabolite Y (*b*) by mass spectroscopy. Mass spectra of metabolite isolated from ethylene-exposed pea tissue and of authentic ethylene glycol (*a*) were obtained by scanning effluent peaks from a Chromosorb 101 GC column, heated from 75 °C to 190 °C at 15 °C min^{-1}, with a Vacuum Generators 16F mass spectrometer. Because of the low concentration of metabolite in the extract its three weakest mass peaks were below the detection threshold and hence were absent from its spectrum.

Pea seedlings were surface sterilised as described previously[5] and germinated in the dark in sterile vermiculite. After 5 d the upper halves of the seedlings were removed, placed in glass stoppered flasks with 4 ml distilled water and exposed in the dark at 24 °C to 10 μl l^{-1} ^{14}C-labelled ethylene (Amersham,

0028–0836/80/010066—03$01.00

120 mCi mmol^{-1}) purified by preparative gas chromatography[11]. Incubation flasks contained a side-well with 1 ml 1 M NaOH to trap evolved CO_2. After exposure for 1 or 2 d, epicotyls were removed and a 50% ethanol extract of the tissue was prepared. After centrifugation the extract was freed of acids and bases by passage through columns of cationic and anionic exchange resins (AG50W-X8 and AG1-X8, Bio-Rad). Paper chromatography of the resulting neutral extract revealed two ^{14}C-labelled metabolites (Fig. 1*a*). The faster moving metabolite Y was investigated first because short-term labelling and pulse chase experiments indicated that it was formed before X. When compared to various neutral standard compounds, including oxidation products of ethylene, it always co-migrated with ethylene glycol (Table 1).

For confirmation by mass spectrometry, seedlings were grown in large trays for 5 d and exposed to 1,000 μl l^{-1} unlabelled ethylene for 2 d. Epicotyls were then collected and from 2,700 g fresh weight of tissue a neutral ethanol extract was prepared, spiked with ^{14}C-labelled metabolite Y, and purified for gas chromatography-mass spectrometry (GC-MS) using ion-exchange chromatography, acetonitrile precipitation and HPLC (silica column, mobile phase of butyl chloride : methanol : H_2O, 830 : 170 : 5). The mass spectrum of the Y peak emerging from a Chromosorb 101 GC column was of low intensity but essentially identical to that of authentic ethylene glycol (Fig. 2).

In similar studies with the ethylene mimic propylene, exposure of pea epicotyls to 10 μl l^{-1} of purified ^{14}C-labelled propylene (Amersham, 3 mCi mmol^{-1}) formed three ^{14}C-labelled metabolites (Fig. 1*b*). Co-chromatography with authentic material clearly showed that propylene metabolite A was 1,2-propanediol (Table 2), and GC-MS analysis of a purified sample from pea epicotyls provided positive identification (Fig. 3).

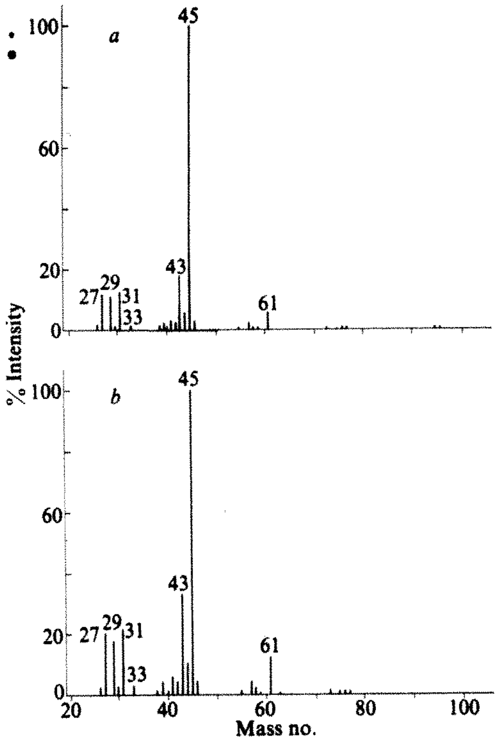

Fig. 3 Identification of propylene metabolite A (*b*) by mass spectroscopy. Mass spectra of purified metabolite from propylene-exposed pea tissue and of authentic 1,2-propanediol (*a*) were obtained as in Fig. 2.

Ethylene metabolite X and propylene metabolite C have been identified as glucose conjugates of ethylene glycol and 1,2-propanediol, respectively, and treatment of either with β-glucosidase yields the corresponding glycol. The formation of metabolites X and Y appears to be a general phenomenon associated with the physiological chemistry of ethylene in plants as we have detected them in a variety of tissues exposed to $^{14}C_2H_4$, including pea epicotyl tissue, carnation ovary tissue, morning glory flowers, cotton abscission zone segments and tomato fruit.

Table 1 Co-chromatography of ethylene metabolite Y and ethylene glycol

Chromatographic system	Solid phase	Mobile phase	Retention time or R_f value ^{14}C-ethylene metabolite Y	 Ethylene glycol
Liquid	Silica column	Acetonitrile : water (85 : 15)	6.50 min	6.41 min
Liquid	Silica column	Butyl chloride : methanol : water (75 : 25 : 0.5)	9.90 min	9.82 min
Liquid	Amine-bonded silica column	Acetonitrile : water (199 : 1)	3.70 min	3.70 min
Gas	Chromosorb 101 column, 200 °C	Helium	2.45 min	2.46 min
Thin layer	Cellulose	Ethyl acetate : acetic acid : formic acid : water (18 : 3 : 1 : 4)	0.72 (R_f)	0.72 (R_f)
Paper	Cellulose	Butanol : acetic acid : water (3 : 3 : 2)	0.64 (R_f)	0.65 (R_f)

^{14}C-ethylene metabolite Y was detected by scintillation counting in all systems. Ethylene glycol was detected by monitoring the refractive index in liquid systems, by flame ionisation in the gas system, and by scintillation counting of authentic ^{14}C-ethylene glycol in thin layer and paper systems.

Table 2 Co-chromatography of propylene metabolite A and 1,2-propanediol

Chromatographic system	Solid phase	Mobile phase	Retention time or R_f value ^{14}C-propylene metabolite A	 1,2-Propanediol
Liquid	Silica column	Butyl chloride : methanol : water (75 : 25 : 0.5)	7.59 min	7.65 min
Liquid	Silica column	Acetonitrile : water (98 : 2)	8.08 min	8.00 min
Liquid	Nitrile-bonded silica column	Butyl chloride : methanol : water (85 : 15 : 0.5)	7.87 min	7.85 min
Gas	Chromosorb 101 column, 200 °C	Helium	2.90 min	2.90 min
Thin layer	Silica	Butyl chloride : methanol : water (75 : 25 : 0.5)	0.50 (R_f)	0.48 (R_f)
Thin layer	Silica	Acetonitrile : water (95 : 5)	0.58 (R_f)	0.60 (R_f)

^{14}C-propylene metabolite A was detected by scintillation counting in all systems. 1,2-Propanediol was detected by monitoring the refractive index in liquid systems, by flame ionisation in the gas system, and by I_2 vapour staining in thin layer systems.

To our knowledge this is the first report demonstrating that higher plants oxidise ethylene to ethylene glycol. The importance of this oxidative process stems from its apparent direct involvement in the mechanism of action of this hormone[7]. It has been suggested[6] that this metabolism might occur at a Cu-containing receptor site, and this notion is supported by the sensitivity of this system to Cu chelators, COS and CS_2 (ref. 8). In nonbiological aqueous systems $Cu–C_2H_4$ complexes can undergo oxidation to yield ethylene oxide[12], and in *Vicia faba* L. cotyledons[13] ethylene was recently shown to be rapidly converted to this product. Although this rapid conversion seems to be unique to this tissue (ref. 14 and M. A. Hall, personal communication), it is of interest because ethylene oxide is a likely precursor of ethylene glycol. In conditions like those found in *Vicia faba* cotyledons, where ethylene is rapidly metabolised, perhaps ethylene oxide escapes before undergoing hydrolysis, or this latter step may be blocked in this tissue. Precedent for this can be found in microbial systems where epoxidation of ethylene apparently occurs but not glycol formation[15].

We thank Fulton G. Kitson for GC-MS analysis of the metabolites.

Light-dependent synthesis of cholecalciferol in a green plant

Hermann Zucker, Heidi Stark & Walter A. Rambeck

Institute for Physiology, Physiological Chemistry and Nutrition Physiology, Veterinary Faculty, Ludwig-Maximilians-University, D-8000 Munich, FRG

Cholecalciferol (vitamin D_3) and several of its metabolites participate in the regulation of calcium and phosphorus metabolism in higher vertebrates (see refs 1, 2 for reviews). In contrast to the synthesis of ergocalciferol, the vitamin D of plant origin, cholecalciferol synthesis has been considered to be confined to skin lipids of vertebrates. Its 6,7-*cis*-intermediate, precalciferol[3], is formed by a photoreaction (wavelength 250–310 nm) from 7-dehydrocholesterol in or on skin tissue. Recently, however, a metabolite of cholecalciferol, 1,25-dihydrocholecalciferol, previously known to be synthesised only in mammalian and avian kidneys, has been detected in at least two species of Solanaceae[4,5]. Furthermore, Rambeck *et al.*[6] showed that cholecalciferol occurs in the common grass, *Trisetum flavescens*, which had been identified by Dirksen *et al.*[7] as the cause of calcinosis in grazing cattle. We now demonstrate that cholecalciferol is formed in *T. flavescens* only in the presence of UV light, thus suggesting a similar path of synthesis in plants to that which occurs in vertebrates.

For the present studies, *T. flavescens* and other grasses were sown in a dark room in wooden frames containing finely sieved soil and covered by cubic tents of aluminium foil to exclude all radiation from the outside. Inside, Grolux lamps of 30 W each were placed 60 cm above the soil surface. Spectral energy distribution as measured at soil level was: 780–400 nm, 97.5%; 400–315 nm, 2.1%; 315–280 nm, 0.4%. To exclude UV light entirely, yellow Plexiglass filters, which absorb wavelengths <490 nm, could be inserted horizontally beneath the lamps. Growth, as judged by appearance and dry matter yield per m^2, was not noticeably influenced by the absence of UV light. The grass was cut after 4–6 weeks and freeze dried taking care to prevent exposure to any source of light.

Table 1 Influence of *T. flavescens* grown with and without UV light on rat inorganic serum phosphorus (mg P per 100 ml)

	Test 1	Test 2	Test 3
Concentration of *T. flavescens* dry matter in test diet	6%	3%	2%
+UV grown	4.2±0.9	4.5±0.6	3.1±0.5
−UV grown	2.6±0.5	2.7±0.4	2.2±0.6
Negative control	1.4±0.1	2.5±1.1	1.7±0.4
Negative control + vitamin D_3	3.3±0.7	3.7±0.3	—

Weanling rats are placed on a vitamin D-free diet containing ~0.5% total P. Calcium concentration is ~0.4% for 14 days and is reduced to ~0.1% during the third week. The experimental diets, containing the respective vitamin D sources and ~4% Ca, are then given for 3 days.This change in Ca intake leads to a sudden drop in serum P from 9–12 to 1.5–2.5 mg per 100 ml. Orally administered vitamin D reduces this drop in P_i serum levels. P_i was measured 65 h after the diet switch. Six individually kept rats were used for each treatment.

The vitamin D activity of the samples was tested by the same procedure previously used for the purification and isolation of cholecalciferol from *T. flavescens*[6]. This test uses an acute, drastic drop in inorganic serum phosphorus level which is induced by dietary means in the rat and can be prevented by administration of vitamin D (see Table 1 legend). *T. flavescens* grown without UV light showed significantly less, but still some vitamin D activity compared with *T. flavescens* grown without the filters in three independent replications (Table 1). As we suspected that traces of light may have led to some vitamin D activity, in the following experiments, the final steps of preparation were carried out in total darkness. As an additional control, an equivalent amount of diethyl ether extract from *T. flavescens* grown without UV was tested after a short exposure to a UV lamp.

The results, shown in Table 2, indicate that vitamin D activity is completely dependent on UV exposure, and, in addition, that a single exposure of quite short duration, as was the case with the extract, results in considerable vitamin D activity. Therefore, UV radiation is unlikely to be a limiting factor of cholecalciferol synthesis in this plant even in natural growing conditions.

Further experiments, to be reported in detail elsewhere, showed that the vitamin D activity is mainly confined to the leaves[8]. The concentration of cholecalciferol as estimated by the quail eggshell test[9], rat test, GC and HPLC ranged from about 0.05 to 0.15 mg per kg of whole plant dry matter. Cholecalciferol concentration seems to be independent of the stage of vegetation, first or second cutting, soil, geographical area and altitude above sea level. Differences are due to the proportions of young leafy parts. Five different breeds of *T. flavescens* were of similar activity. However, samples of *Trisetum elatior* (*Avena elatior, Arrhenatherum elatius* L.), closely related to *T. flavescens*, were entirely inactive. A very small, insignificant elevation of inorganic serum phosphorus was obtained in our tests from

0028–0836/80/010068—02$01.00

Table 2 Influence of UV light on vitamin D activity of *T. flavescens* and *T. flavescens* extract as measured by inorganic serum phosphorus (mg P per 100 ml)

Concentration of *T. flavescens* dry matter (or extract aliquot) in test diet	3%	3%
+UV grown	3.7 ± 0.6	—
−UV grown	2.0 ± 0.3	—
−UV grown extract UV exposed	—	4.0 ± 0.5
Negative control	2.4 ± 0.6	2.6 ± 0.6
Negative control + vitamin D_3	4.3 ± 0.7	3.5 ± 0.6

For methods see Table 1 legend. The extract from lyophilised *T. flavescens* (grown without UV) was prepared by diethyl ether extraction as described by Rambeck *et al.* and placed for 3 min under a laboratory UV lamp[6].

samples of *Dactylis glomerata*. This widely occurring grass had been reported earlier[10] to contain cholecalciferol, although the concentration was not mentioned. Cholecalciferol or its immediate precursors had not been detected in a study of sterol distribution in pasture grasses, which included *T. flavescens*[11]. This may have been due to the low concentration, which necessitates rather refined techniques for its detection[6].

Our results are the first demonstration of a UV light-dependent synthesis of cholecalciferol in an autotrophic plant. (We have previously shown[6] that the total vitamin D activity of *T. flavescens* can be attributed to cholecalciferol rather than to any of its metabolites.) Our findings may have some relevance to hitherto unresolved questions concerning the ultimate origin of cholecalciferol in the livers of marine fish. Holick *et al.*[12] recently reported that some marine fish are incapable of synthesising cholecalciferol in the absence of UV light and may not even metabolise cholecalciferol. Thus, cholecalciferol may be a rather inert constituent of the marine food chain, produced by as yet unidentified species of the autotrophic phytoplankton in the upper strata of the oceans, where some penetrating UV radiation may suffice for its synthesis in plant cells. The functions of 'vitamin D' in plant cells are unknown, but a stimulatory effect of high concentrations of vitamin D analogues, including cholecalciferol, on rhizogenesis was recently reported by Buchala and Schmid[13].

We thank Professor Hartmann, University of Munich, for advice on UV filters and the control measurements mentioned in the paper, and Mrs Ortrud Kreutzberg and Mrs Antje Wetzel for technical assistance. This work was supported by the Deutsche Forschungsgemeinschaft.

A square bacterium

A. E. Walsby

Marine Science Laboratories, Menai Bridge, Gwynedd, UK

I have come across a bacterium which has the form of a thin square sheet. In most bacteria such a shape would be precluded by the osmotically-generated internal hydrostatic pressure but this organism, found in a saturated brine pool, has little or no cell turgor pressure. Its shape is probably determined by the pattern in which the cell envelope particles assemble. These square bacteria are so thin and transparent and are so unlike any bacteria previously described that I would have overlooked them if they had not possessed gas vacuoles, and I had not been looking for different forms of gas-vacuolate organisms. The squares derive buoyancy from their gas vacuoles and float at the brine surface.

Gas vacuoles are found exclusively in prokaryotic organisms and occur mainly in planktonic forms[1,2]. It has been proposed that, through providing or regulating buoyancy, they are important in positioning these organisms at particular depths in natural waters[2]. Surveys of freshwater lakes[3,4] suggest that gas-vacuolate bacteria are to be found in all lakes which are stable or stratified and I wondered whether this applied also to saline pools. Gas-vacuolate bacteria of the genus *Halobacterium* have been isolated from solar salt[5] and it has been speculated that their gas vacuoles buoy them to the surface of brine pools where the oxygen these obligate aerobes require is more readily available[6]. However, this has yet to be substantiated by field observations[2].

I collected brine from a salt crust forming at the surface of a hypersaline pool in a sabkra (a coastal plain at sea level) just south of Nabq, on the Sinai Peninsula. The chemistry of the pool and its location are described in detail by Krumbein *et al.*[7]. Microscopic examination revealed abundant gas-vacuolate organisms. At least five morphologically distinct forms were present, and of these the square bacteria were most abundant. Using a Hawksley standard counting chamber, I estimated that there were 7×10^7 squares per ml of liquid brine.

The presence of gas vacuoles in the various forms was demonstrated by comparing the appearance of individual cells before and after application of pressure (Fig. 1) as described previously[3]. Gas vacuoles are made up of minute hollow, proteinaceous structures called gas vesicles[8]. By virtue of their small size and the low refractive index of their contents, they scatter light very strongly and show as brilliant light objects against the dark ground of the cytoplasm under the phase contrast microscope. However, they can be made to collapse irreversibly by application of pressure and then they are no longer visible. This disappearance is diagnostic of gas vesicles—and the gas vacuoles they form—and identifies them unambiguously[2,3]. The presence of gas vacuoles in the squares firmly established their bacterial nature. Attempts to culture the organism were unsuccessful, but samples of brine were enriched for the square bacterium by centrifugation, as follows. A drop of the sample was mixed with the saline solution described below and placed in a haematocrit tube, forming a layer 18 mm deep. The tube was centrifuged at 227*g* for 100 min. The pressure generated at the base of the tube in these conditions was only 0.4 bars, too small to collapse a significant quantity of vesicles[9]. The buoyant, gas-vacuolate square bacteria rose to the meniscus from where they could be transferred by microsyringe. The squares also aggregated at the meniscus of the brine sample after leaving it to stand for two days. The squares which floated in contact with the coverslip of the counting chamber sank after application of pressures causing gas vacuole collapse. This showed that the square bacteria depended on their gas vacuoles for buoyancy.

0028–0836/80/010069—03$01.00

The membranous appearance of the squares at first suggested that they might be the walls of other disintegrated bacteria to which gas vacuoles had remained attached. However, some of the sheets, >20 μm^2, were clearly too large for this. Moreover, the thickness of the sheets, 0.2–0.5 μm, which could just be discerned from edge-on views, would be too much for a simple wall but just enough for a bacterium. This interpretation was supported by finding cells which were evidently in various stages of division (Fig. 2). The gas vacuoles were frequently concentrated around the edges of the squares and along the presumptive division lines. Undivided squares ranged in size from 1.5 to 11 μm (Fig. 2). Some squares had a number of division lines (strictly speaking, planes). Their arrangement indicated that the division occurred in two planes alternating at right angles; this produced sheets divided like postage stamps. Sheets of eight squares were not uncommon and sheets of 16 were found with individual squares tearing free.

Electron microscopy was carried out on samples of brine enriched for the square bacteria. The gas vesicles, which could be seen in whole-mounted unstained preparations, were similar to those of other bacteria, cylinders with cone-shaped ends[1,2]. Metal shadowing showed that the surface of the square bacteria was covered in particles ~2 nm across, arranged in a regular hexagonal lattice. This is similar to the arrangement observed in halobacteria[10] and suggests that, like them, the square bacteria belong to the group designated Archaebacteria[11]. Another feature of this group, satisfied by both, is that they occur in extreme environments. However, the phylogenetic relationships of the square bacterium can be established only by analysis of material from axenic cultures.

The regular array into which the cell envelope particles are assembled presumably determines the shape of the square bacterium. It is postulated that such a shape is permitted only by the absence of turgor pressure in this organism.

The majority of known bacteria have shapes such as spheres, ellipsoids or cylinders which are suitable for withstanding internal pressure. However, if pressure were generated in the square bacterium the flat surfaces would tend to bow outwards, break or come apart at the joining edges. Because the squares are obviously stable and remain flat they must have a low turgor pressure inside them. Another extreme halophile with gas vacuoles, *Halobacterium* sp.[12] has no detectible turgor pressure[13] and may, in certain conditions, produce rather flattened cells[10]. (*Simonsiella* spp. also have flattened cells, arranged in filaments[14], but nothing is known of their osmotic relationships.)

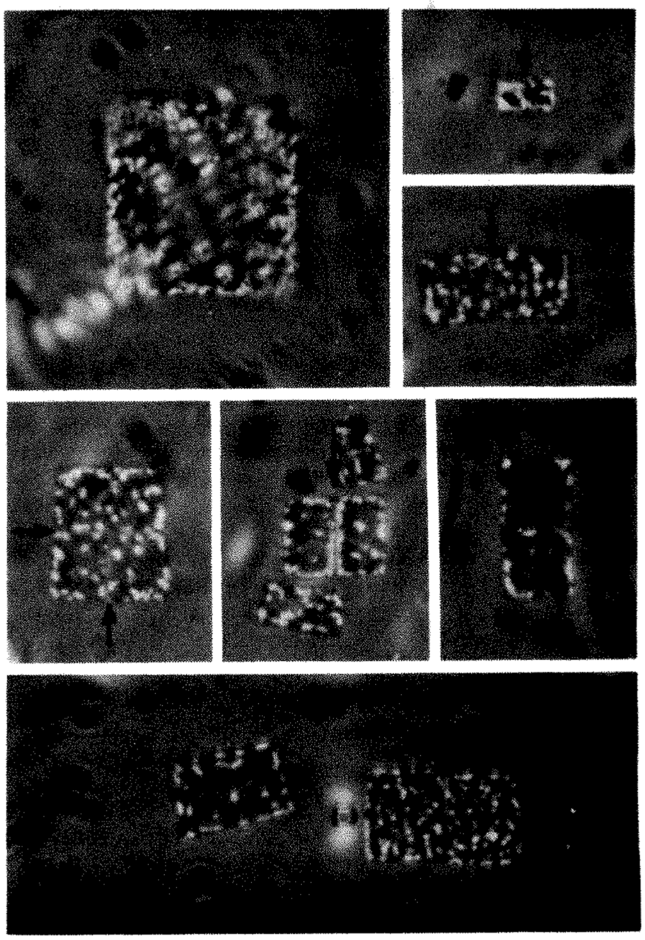

Fig. 2 Phase contrast light micrographs of the square bacterium illustrating the range of cell size. The light areas are gas vacuoles. Division lines, just detectable on the original print are indicated by the arrows. Scale bar, 10 μm.

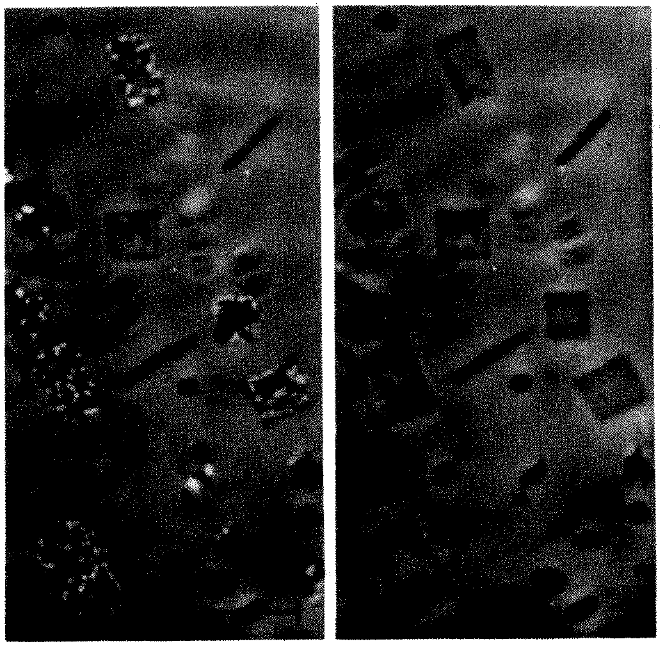

Fig. 1 Phase contrast light micrograph of a field of square bacteria seen before (on the left) and after (right) application of 5 bars pressure which causes the gas vacuoles to disappear. Scale bar 10 μm.

Cell turgor pressure can, in principle, be measured in any prokaryote which contains gas vacuoles. The constituent gas vesicles collapse irreversibly over a well-defined range of pressure. Inside the cell, turgor pressure contributes to the pressure required but if a non-penetrating solute, such as surcrose, is added to the suspending medium the turgor pressure is reduced and the pressure required to collapse the gas vesicles rises accordingly. Measurements on various freshwater prokaryotes suspended first in water and then in hypertonic sucrose solutions have revealed turgor pressures of mainly 2–5 bars[13], and increases in such pressures over this range cause the cells to swell[15]. The unusual absence of turgor in halobacteria is evidently related to the high salt concentration of their surroundings[13].

Accurate measurements of turgor pressure by the gas-vacuole method require small but homogeneous suspensions of the organism, though a rough estimate can be made from observations on the disappearance of gas vesicles in individual cells under the microscope. A 4-μl sample of the brine was mixed with 15 μl of 1 M sucrose dissolved in a salt solution containing NaCl (250 $g\,l^{-1}$), KCl (5 $g\,l^{-1}$), $MgSO_4$ (10 $g\,l^{-1}$) and $CaCl_2$ (0.13 $g\,l^{-1}$), the main mineral ingredients of a halobacterium culture medium[16]. A control sample was mixed with the same salt solution without sucrose. Drops of the mixtures were placed on Hawksley counting chambers, depth 0.02 mm, and a coverslip was positioned acentrically to provide an air gap to the channel surrounding the platform[3]. The bacteria were observed under phase contrast illumination using a ×1,000 oil immersion objective and again after pressurising the slide at 1, 1.5, 2, 2.5, 3 and 10 bars. Individual gas vesicles could be seen but not separately resolved at this magnification. In both mixtures with and without sucrose a definite reduction in gas vesicle numbers per cell was seen after application of 1.5 bars, most of the vesicles had disappeared by 2.5 bars, and none remained beyond 3 bars. The lack of difference between the two samples with respect to the pressure required to collapse gas vesicles shows that turgor pressure was small or non-existent[13].

In the absence of turgor pressure there is no obvious constraint on the shape of a bacterium and in theory any shape might be adopted, depending on the shape and arrangement of units which make up the cell wall. Whatever determines its shape apparently allows for some variation as occasionally triangular and trapezoid shapes are seen. These appear to be complete cells and not simply squares which have been folded or torn. The similarity in shape of the bacterium and the salt crystals with which it coexists is probably fortuitous.

The brine sample was collected on a visit kindly arranged by Professor Moshe Shilo and supported by the Royal Society. I thank Professor Wolfgang Krumbein for his geomicrobiological tour of Sinai and the brine pool, and Mr Ken Parkes for the electron microscopy.

Cytoplasmic incompatibility in natural populations of a mosquito, *Culex pipiens* L.

A. Ralph Barr

Division of Epidemiology, School of Public Health,
University of California, Los Angeles, California 90024

When two strains of *Culex pipiens* (s.l.) of different geographical origin are cross-mated, the cross is frequently sterile in one or both directions[1]. Such incompatibility is said to be cytoplasmic because the crossability of a strain is determined by its maternal lineage[2]. The incompatibility is caused in some way by infection with a rickettsia-like bacterial symbiote, as removal of the symbiote abolishes the incompatibility[3]. Incompatibility has not been observed in crosses of American strains of *C. pipiens*[4–7]. On the other hand, most workers in other parts of the world who have crossed *C. pipiens* strains have noticed incompatibility[7–14], although there are no reports of incompatible egg rafts being collected in the field. We now report incompatibility in crosses of sympatric American strains of *C. pipiens* and the collection of incompatible egg rafts in the field.

On 4 July 1978, an egg raft of *Culex pipiens quinquefasciatus* Say was collected in Malibu, Los Angeles County, California. Its appearance suggested that the egg raft had been laid by a female which mated with an incompatible male; about 80% of the eggs showed evidence of embryonic development and few of these had developing setae visible, indicating that the embryos died early in development. About 20% of the eggs did not show evidence of embryonic development, and these were scattered throughout the raft rather than being in a group at one end. Three similar rafts have been collected from the same breeding place, on 15 July, 24 July and 22 August 1978. So far, 48 egg rafts have been examined from this breeding place, of which 43 hatched normally, 4 were apparently incompatible, and 1 showed no embryonic development at all, which indicates that it was probably laid by an uninseminated female.

Table 1 Crossing types of egg rafts collected in southern California

Locality	Crossing type* A	B	C	Total
Malibu	31	1	1	33
West Covina	8	1	0	9
West Los Angeles	7	0	1	8
Venice	3	0	0	3
Mar Vista	15	0	1	16
Total	64	2	3	69

* A, Reciprocally compatible with Californian crossing type; B, females incompatible with males of Californian crossing type, reciprocal cross compatible; C, males incompatible with females of Californian crossing type, reciprocal cross compatible.

After the second incompatible egg raft was observed (15 July), all egg rafts collected were taken to the laboratory, allowed to hatch, the larvae reared, and the adults reciprocally crossed with a mongrel *C. pipiens* laboratory strain of Californian crossing type (here designated crossing type A). Adults were placed in small cages (1.5-l capacity) and females fed on human or mouse blood. Thirty-three progenies have now been successfully tested; 31 were compatible when crossed in either direction with the laboratory strain. The females of one progeny (crossing type B) were incompatible when crossed with males of the laboratory strain, although the reciprocal cross was fertile. The males of another progeny (crossing type C) were incompatible with females of the laboratory strain, although the reciprocal cross was fertile.

In three other localities in greater Los Angeles (West Covina, West Los Angeles, Mar Vista), mixed populations of crossing types have also been found (Table 1), although incompatible egg rafts have not yet been taken in the field in these locations.

A laboratory strain was developed from sibling females of crossing type C which had been crossed with males of type A. In the F_4 of this strain, 10 of 60 egg rafts examined were incompatible. In the F_5, 2 of 39 examined were incompatible. This is the first report of incompatibility between individuals from a common female ancestor, although in this case the incompatible individuals may have been third or fourth cousins.

Variation in crossing type in the progeny of a female has been reported twice before[15,16], but incompatibility between individuals derived ultimately from a single female has not been reported. The present data suggest that there may be a mixed population of crossing type determinants in a female and these may segregate in her progeny to produce incompatibility in crosses between siblings. The cost of this incompatibility may be judged by the fact that 4 of 47 (8.5%) egg rafts of inseminated females taken at the Malibu breeding place failed to produce larvae.

It has been argued that two incompatible crossing types cannot exist for long in the same population because one type will eliminate the other in a fairly short time[17]. This argument is based on the assumption that each crossing type is invariable. It now seems probable that an individual mosquito may contain symbiotes producing two different and incompatible crossing types. A female may thus produce offspring which are of more than one crossing type and some offspring may be incompatible when mated with their siblings. Incompatibility in this case is a less effective selective agent for ridding the population of the incompatible crossing type. Incompatibility may thus persist in a natural population for a long time even though it is selected

0028–0836/80/010071—02$01.00

against when expressed. The consequence for the host population is reproductive waste and for the symbiotes a reduction in fitness of their hosts.

I thank Sylvia Barr, John de la Fuente, Pensri Guptavanij, Umaima Saifuddin, Osamu Suenaga and Theresa Sweeny for technical assistance, and Virginia Hansen for editorial support. This research was supported by PHS grant no. AI 11847.

Influence of H-2 complex on acquired resistance to *Leishmania donovani* infection in mice

Jenefer Blackwell, Joan Freeman & David Bradley

Ross Institute of Tropical Hygiene, London School of Hygiene and Tropical Medicine, Keppel Street, London, WC1

Innate susceptibility to *Leishmania donovani* infection in mice (measured over 2–4 weeks) is under the control of a single autosomal gene (*Lsh*) segregating for incompletely dominant resistant (*r*) and recessive susceptible (*s*) alleles[1]. This locus maps[2] away from the known histocompatibility loci to a position between the centromere and *Id-1* on the chromosome 1 of the mouse. Amongst homozygous recessive *Lsh*^{s} strains of mice two patterns of recovery are observed[3] when the course of infection is followed over a longer term. In some strains a dramatic fall in parasite numbers with histological liver damage occurs while other strains maintain immense parasite loads for up to two years involving mononuclear phagocytes throughout the body. We now present evidence which suggests that this difference in long-term response is largely controlled by a gene(s) within, or closely adjacent to, the major histocompatibility complex (H-2) of the mouse.

Initially C57BL/10ScSn and B10.D2/n congeneic mice plus their F_1, F_2 and backcross progeny were infected with *L. donovani* and the course of their infections followed over 130 days. In the parental strains all of the B10.D2/n mice maintained heavy infections over the 130 days while liver parasite burdens in C57BL/10ScSn mice began to fall by day 50. All of the F_1 and backcross to B10.D2/n mice followed the B10.D2/n pattern of long-term high infections. F_2 and backcross to C57BL/10ScSn mice appeared to be segregating for high and low parasite burdens by days 85 and 130. When graphed according to H-2 haplotype (Fig. 1), H-$2^{d/d}$ and H-$2^{b/d}$ mice always maintained long-term heavy infections while H-$2^{b/b}$ mice showed a reduction in parasite load. Although the time course for the early stage of this recovery differed slightly between experiments, a significant difference between H-$2^{b/b}$ and H-$2^{b/d}$ mice and between H-$2^{b/b}$ and H-$2^{d/d}$ mice was always observed 85 days after infection. H-$2^{b/d}$ and H-$2^{d/d}$ mice never differed significantly during the 130 days over which infections were followed. We concluded, therefore, that a gene(s) within, or closely adjacent to, H-2 controls an acquired resistance mechanism which behaves as a recessive trait and allows some innately susceptible mice to recover from an initially heavy infection of *L. donovani*. We propose *Rld-1* (recovery from *L. donovani*) as the provisional designation for this locus following the pattern laid down for H-2 linked genes controlling resistance to Gross leukaemia virus (*Rgv-1*)[6], Friend virus leukaemogenesis (*Rfv-1*)[7], and radiation leukaemia virus (*Rrv-1*)[8]. The two phenotypic patterns of long term infection we refer to as 'cure' and 'noncure'.

Following this discovery, four other H-2 haplotypes (*q*, *f*, *s* and *r*) on a B10 genetic background were tested for long-term response to *L. donovani* infection (Figs 2 and 3). The *q* (strain B10.G) mice showed the typical 'noncure' response, never differing significantly from control B10.D2/n and (B10.D2/n × C57BL/10ScSn)F_1 mice. The *f* (strain B10.M) mice also showed

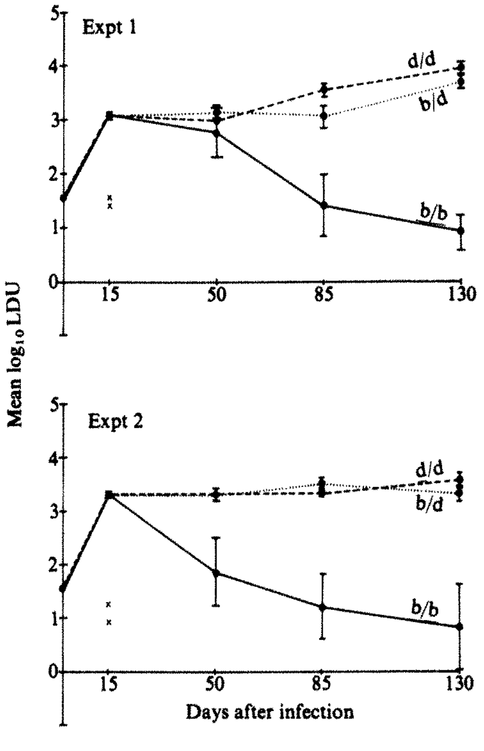

Fig. 1 For each experiment, groups of 10 mice from strains C57BL/10ScSn and B10.D2/n and from their F_1, F_2 and backcross progenies (London Hospital Immunology Department) were infected with 10^7 amastigotes *L. donovani* as described by Bradley and Kirkley[3]. Two mice from each group were killed on days 15, 50 and 85 following infection and four mice from each group on day 130. The number of parasites per 500 liver cell nuclei were counted from Giemsa-stained impression smears and the results expressed as 'Leishman Donovan units' (LDU)[4]. All mice except those killed on day 15 were individually H–2 haplotyped using microcytotoxicity testing[5] with two NIH private specificity antisera for each end (K and D) of H–2. Results graphed are mean $\log_{10}$LDU counts (±1s.e.) against days after infection for mice grouped according to the haplotypes: homozygous *b/b*, heterozygous *b/d*, and homozygous *d/d*. The day 0 points on the graphs represent approximately 70% uptake of the initial dose of amastigotes by the liver Kupffer cells found in many strains of mice by Bradley and Kirkley[3]. Since C57BL/10ScSn and B10.D2/n mice do not differ significantly in their day 15 parasite burdens[1], counts for all mice were pooled to obtain the day 15 points on the graphs. This is further justified by the very small standard errors (0.05 and 0.04) obtained for the 12 mice killed on day 15 in each experiment. Crosses (×) represent individual counts from control homozygous *Lsh*^{r} mice (C3H/He-*mg*/Ola and C57L) included in each experiment. Student's *t*-tests were used to test when differences in mean parasite loads between mice of different haplotypes became statistically significant. In both experiments *b/b* mice had significantly lower parasite loads than either *b/d* or *d/d* mice on days 85 ($P<0.02$) and 130 ($P<0.001$). In the second experiment the day 50 counts for *b/b* mice were already significantly lower ($P<0.02$). Mice of *b/d* and *d/d* haplotypes never differed significantly from each other.

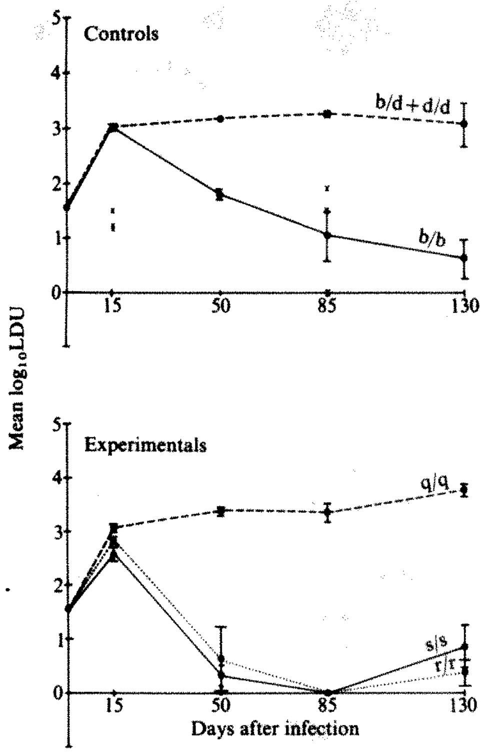

Fig. 2 Mice with *q*, *s* and *r* H–2 haplotypes on a B10 genetic background were tested for longterm response to *L. donovani* by infecting 17 B10.G/Ola, 15 B10.S/Ola and 15 B10.RIII(71NS)/Ola mice. For the B10.G strain, four mice were killed on each of days 15, 50 and 130 and five mice on day 85. For B10.S and B10.RIII strains, three mice were killed on day 15 and 4 mice on each of the days 50, 85 and 130. Control 'cure' and 'noncure' mice included 12 C57BL/10ScSn (Olac and Nuffield Foundation), 6(B10.D2/n × C57BL/10ScSn)F1 and 4 B10.D2/n/Ola mice. Since *d*/*d* (B10.D2/n) and *b*/*d* (F_1) mice do not differ significantly in their long-term response (Fig. 1), mice from these two groups were pooled as the 'noncure' control. Only three control mice were killed on the early days of infection allowing four 'cure' and four 'noncure' mice to be killed on each of days 85 and 130. Results graphed are mean $\log_{10}$LDU counts (±1 s.e.) for each group of mice against days after infection. Mean log counts for B10.S and B10.RIII mice did not differ significantly throughout the experiment. Neither did B10.G differ from control 'noncure' mice. B10.S and B10.RIII mice had significantly lower mean log counts on day 15 than both B10.G ($P<0.05$) and the control 'cure' and 'noncure' mice ($P<0.05$). Mean day 15 LDU counts for these two strains were still, however, 28-fold higher than mean LDU counts from homozygous Lsh^r mice (C3H/He-*mg*/Ola mice indicated by ×). Mean log counts also declined earlier in these two strains than in control 'cure' mice (day 50, $P<0.01$). This difference was no longer present on days 85 and 130. The levels of parasitaemia maintained in 'cure' mice at this stage in infection falls close to or below the threshold level for finding one parasite on an impression smear[9] and any slight differences between days and between strains are magnified by the log scale required to graph the extreme differences in parasite loads between 'cure' and 'noncure' mice. Hence we place no significance on the apparent increase in parasite loads between days 85 and 130 in B10.S and B10.RIII mice. These low levels of parasitaemia are of the same order of magnitude as those maintained in innately resistant (Lsh^r) mice (this experiment day 85 and Bradley and Kirkley[3]).

an essentially 'noncure' response. Although logLDU counts for these mice were slightly lower than control 'noncure' mice throughout the experiment, the difference only reached statistical significance ($P<0.01$) on day 85. Day 130 counts did not differ significantly between f haplotype and control 'noncure' mice. A significant difference was, however, observed between f haplotype and control 'cure' mice on days 85 ($P<0.01$) and 130 ($P<0.001$). The *s* (strain B10.S) and *r* (strain B10.RIII) haplotype mice displayed an acquired resistance mechanism similar to, but effective earlier than, that observed in C57BL/10ScSn *b* haplotype mice. Day 15 parasite levels in these two strains indicated that this acquired resistance mechanism may be operating sufficiently early to modify *Lsh* gene control of innate susceptibility. Parasite burdens were still, however, 28-fold higher than those observed in Lsh^r mice.

Our finding that 'cure' behaves as a recessive trait in H–$2^{b/d}$ mice is unusual in that most H–2 linked *Ir* genes show dominant responsiveness[10]. H–2 linked loci which do control apparent recessive immune responsiveness[7,11–13] do not follow the same distribution of haplotypes between 'responder' and 'nonresponder' strains as we have shown between 'cure' and 'noncure' strains. It is unlikely, therefore, that we are dealing with a known H–2 linked gene. Increasing evidence suggests that apparent recessive immune responsiveness may, in some cases, be due to dominant immune suppressor (*Is*) genes[14–16]. These *Is* genes exhibit many genetic similarities with *Ir* genes and map alongside them in the I region of the H–2 complex[15,16]. In other cases[7,13] apparent recessive immune responsiveness is controlled by genes mapping away from the I region of H–2 indicating a mechanism which may be quite independent of the *Ir* gene system[17]. If recovery from *L. donovani* infection were observed in other 'cure'/'noncure' heterozygotes, an immune suppression mechanism rather than recessive immune responsiveness would be favoured. We may thus be dealing with more than one locus within H–2, one controlling immune responsiveness and one controlling immune suppression. Varying rates of recovery between different 'cure' haplotypes could then be explained by a gene-dosage hypothesis. Our current examination of various heterozygous haplotypes as well as our attempts to map *Rld-1* within H–2 using recombinant haplotype strains should resolve these questions.

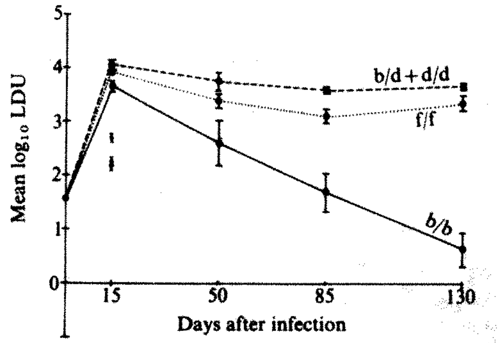

Fig. 3 Mice with the *f* H–2 haplotype on a B10 genetic background were tested for long-term response to *L. donovani* by infecting 15 B10.M/Ola mice. Three mice were killed on day 15, and four mice on each of days 50, 85 and 130. Three control 'cure' C57BL/10ScSn mice and three control 'noncure' (B10.D2/n × C57BL/10ScSn)F_1 mice were killed on each of days 15, 50 and 85, and four mice from each group on day 130. Three control 'noncure' B10.D2/n/Ola mice were also killed on day 85. Results graphed are mean $\log_{10}$LDU counts (±1 s.e.) for each group of mice against days after infection. Mean log counts for B10.M mice were slightly lower than control 'noncure' mice throughout the experiment but differed significantly only on day 85 ($P<0.01$). Control 'cure' mice had significantly lower mean log counts than both B10.M and control 'noncure' mice on days 85 ($P<0.01$, $P<0.001$) and 130 ($P<0.001$ in both cases). Crosses (×) represent individual counts from control homozygous Lsh^r (DBA/2) mice.

Finally, we have attempted to determine whether the acquired resistance mechanism operates for the same H–2 haplotypes on an alternative genetic background. Although chosen because BALB was the only other genetic background carrying the Lsh^s allele, BALB H–2 congenic strains did seem a particularly good choice for this experiment as BALB/c mice were already known to maintain chronic heavy infections involving mononuclear phagocytes throughout the body. BALB/c (*d* haplotype) and BALB/B (*b* haplotype) mice were tested for long-term response to *L. donovani* infection (Fig. 4). The acquired resistance mechanism of the *b* haplotype did appear to operate on the BALB genetic background.

Although marked H–2 restrictions have been demonstrated in the adoptive transfer of resistance to both bacteria[18] and viruses[19], the role of H–2 linked genes in determining actual resistance to infecting agents has previously only been defined for viruses. The present investigation was made possible only by our previous understanding of the genetic control of acute, or innate, immunity to *L. donovani* infection in mice, allowing this

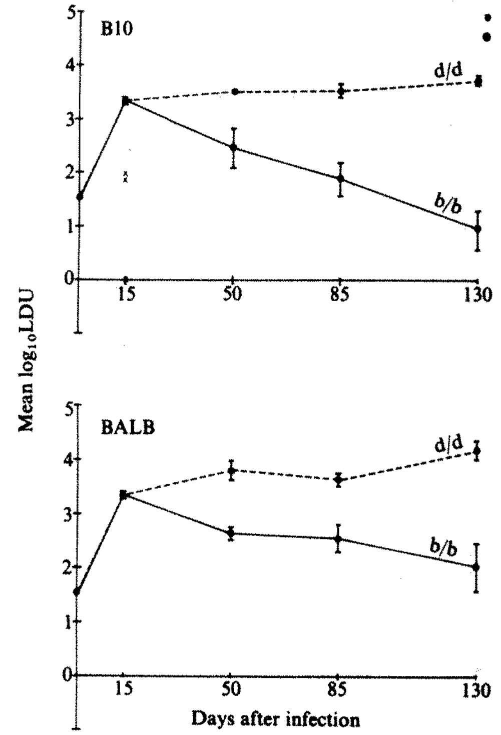

Fig. 4 Mice with *b* and *d* H-2 haplotypes on a BALB genetic background were tested for long-term response to *L. donovani* by infecting eight BALB/B/Ola and 10 BALB/c/Ola mice. For the BALB/B strain, two mice were killed on day 50 and three mice on each of days 85 and 130. For the BALB/c strain, one mouse was killed on day 15 and three mice on each of days 50, 85 and 130. Control 'cure' and 'noncure' mice included 15 C57BL/10ScSn (Olac and Nuffield Foundation) mice and 13 B10.D2/n (Olac and LSHTM) mice. Three mice from each control strain were killed on day 15, 2 on day 50, and five on day 85. Five C57BL/10ScSn and three B10.D2/n mice were killed on day 130. [The low number of BALB mice used in this experiment was due to a shortage in supply and this experiment is being repeated.] Although only one BALB/c mouse was tested here, BALB/c mice are known not to differ significantly in their day 15 mean log counts from C57BL/10ScSn and B10.D2/n mice[1]. We have tested this again many times (unpublished data) and have also subsequently tested the day 15 parasite levels in BALB/B mice. These do not differ significantly from BALB/c, C57BL/10ScSn or B10.D2/n mice. The day 15 points on the graphs therefore represent the mean log count (±1 s.e.) for the seven Lsh^s mice sacrificed on that day. Individual counts for homozygous Lsh^r (CBA/Ca/Ola) mice are indicated by a cross (×). Mean log counts obtained on days 50, 85 and 130 did not differ significantly between BALB/B and C57BL/10ScSn mice or between BALB/c and B10.D2/n mice. Mean log counts for BALB/B mice were significantly lower than BALB/c and B10.D2/n mice on days 50, 85 and 130 ($P<0.02$ in each case), as were C57BL/10ScSn mean log counts ($P<0.01$ in each case).

to be standardised in experiments analysing recovery and acquired immunity. Further study of the mechanisms involved in both the innate and acquired responses will be important to our understanding of this and other related human diseases, particularly in view of the recent implications of HLA linked susceptibility to leprosy[20,21] and malaria[22] in man. The mouse model allows a more precise correlation with major histocompatibility type, more scope for genetic manipulation, and a more direct access to the mechanisms involved.

We thank Professor Hilliard Festenstein and his staff at the London Hospital Immunology Department for providing mice and for assistance with microcytotoxicity tests. Dr Chris Black of the Nuffield Foundation and Dr Mike Steward of the London School of Hygiene and Tropical Medicine supplied C57BL/10ScSn and B10.D2/n mice, respectively. All other mice used were purchased from Olac 1976 Ltd. This work was supported by a grant from the MRC.

Formation of SV40 specific and H-2 restricted target cell antigen by somatic cell fusion

Terri S. Watt & Linda R. Gooding

Division of Immunology, Box 3010, Duke University Medical Center, Durham, North Carolina 27710

Cytotoxic T lymphocytes (CTLs) to syngeneic Simian virus-40 (SV40)-transformed target cells lyse only SV40-transformed cells which are identical to the killer cells at the K and/or D loci of the H-2 complex in mice[1,2]. In fact, CTLs have been shown to require autologous H-2 antigen expression for target cell lysis in a variety of syngeneic systems[3]. The dual specificity of these lymphocytes could indicate that both virus-coded and H-2 gene products are recognised and that interaction between viral and H-2 antigens on the tumour cell surface may be required to form the target antigen. However, serologically detectable SV40-specific antigens have not been found on the transformed cell surface. In addition, antisera to viral proteins do not block T-cell mediated lysis (CML) of syngeneic transformants[4]. If an SV40-specific moiety does not actually exist at the cell membrane, T-cell recognition might occur via an 'altered self' antigen where the virus codes for some activity which alters the H-2 antigens at the level of transcription or translation. To test this hypothesis the following experiments were designed: target cells were 'manufactured' by polyethylene glycol (PEG)-induced fusion of two cell lines; one being syngeneic to the CTL but not SV40 transformed and the other possessing the SV40 genome but differing from the effectors at the H-2 locus. The resulting multinucleated cells (heterokaryons) were then used as targets in the CML assay. Membrane components of heterokaryon cells have been shown to intermix[5]. In the present experiments we reasoned that if the target antigen is an H-2K or H-2D molecule which has been altered in transcription or translation, then simple mixing of membrane components would not lead to target antigen formation and cell lysis. If, on the other hand, separate SV40 induced and H-2 molecules are required for recognition then heterokaryon formation should lead to target antigen expression. Results described below support the latter hypothesis. Furthermore, these results show the simple mixing of cellular components is sufficient for a recognisable target antigen to form, and that protein synthesis is not required.

Cell lines which were chosen as parents for fusion were mixed together and plated on 100-m tissue culture dishes (Falcon). The density at which each cell line was used was determined by the growth rate of that line; slower growing cells were plated at larger numbers than fast growing cells (see Table 1). Cells were ready for fusion with PEG when light monolayers were

H-2^b/SV40*	—		−	—	2%	ND
H-2^b/SV40*	—		+	—	1%	ND
H-2^{k*}	—		−	—	5%	ND
H-2^{k*}	—		+	—	7%	ND
H-2^b/SV40	H-2^k/SV40		+	47%	42%	20%
H-2^d/SV40	H-2^k/SV40		+	45%	46%	34%
H-2^k/SV40	H-2^k		+	59%	37%	ND
H-2^k	H-2^b/SV40		+	43%	21%	21%

Cells were fused using the procedure of Davison and Gerald[6] with slight modifications. Parent cells for fusion were first labelled for 12 h with 100 μCi of $Na_2{}^{51}CrO_4$ (200–500 Ci g^{-1}, NEN, ^{51}Cr), then washed three times in Dulbecco's modified Eagle's medium supplemented with 10% fetal calf serum, 2 mM glutamine and 1.0% antibiotic/antimycotic mixture (Gibco, DME 10), and collected using 0.02% trypsin. Tissue culture dishes (100 mm) were then inoculated with the two parent cell types at the cell densities given and incubated in DME 10 at 37 °C, 5% CO_2 and 95% air. After 12 h the medium was aspirated off and the dishes were washed one time with phosphate-buffered saline (PBS). The cells were then covered with 4 ml of fusing solution (47% polyethylene glycol 6000, Baker, 10% dimethyl sulphoxide, in modified Eagles medium). After 1 min at room temperature the fusing solution was thoroughly rinsed from the dishes with PBS. Dishes were then incubated at 37 °C in DME 10. After 2 h cells were removed with trypsin, washed once with modified Eagles medium containing fetal calf serum, glutamine and antibiotics as above (MEM 10) and an aliquot was removed to determine the efficiency of fusion. One drop of cell suspension was added to one drop of 0.1% acrydine orange-PBS solution and cells were immediately viewed under a Leitz fluorescence microscope. The per cent of the total nuclei present in multinucleated cells was determined and expressed as

$$\text{\% Efficiency of fusion} = \frac{\text{No. nuclei present in multinucleates}}{\text{Total no. of nuclei}} \times 100$$

The fused cell population was expected to contain parent cells, monokaryons and heterokaryons. To reduce the parent cell populations and to minimise homokaryon formation cells were subjected to PEG treatment in conditions which insured maximum fusion. In these conditions most multinulceated cells were found to contain more than 2 and up to 20 or more nuclei. The ^{51}Cr-release assay was performed in triplicate using effectors generated in a secondary *in vitro* sensitisation against H-2^k/SV40 cells as previously described[7] or against allogeneic spleen cells. At the end of the incubation period (6 h) aliquots were removed from assay wells and counted in Beckman Gamma 4000 counter. Results were calculated and are expressed as follows:

$$\text{\% Specific lysis} = \frac{E-C}{T} \times 100\text{, where}$$

E = ^{51}Cr released in the presence of sensitised spleen cells: C = ^{51}Cr released in the presence of non-sensitised spleen cells and T = total ^{51}Cr released by addition of 1 M HCl. Ratio of effector cells to target cells = 50 : 1. Cell lines are designated as follows: PSC3H (H-2^k/SV40), PSSW (H-2^b/SV40), SVBALB (H-2^d/SV40), MM5 (H-2^k). Mouse strains were C3H/HeJ and (B10.D2 × C3H.SW)F$_1$.

* These experiments were run separately and the per cent specific lysis is reported for an effector: target cell ratio of 15 : 1.

achieved. Cells were collected 2h after fusion and the efficiency of the fusion procedure was determined (for details see Table 1).

The efficiency of fusion was usually found to be between 50 and 80% and was probably dependent on the density and arrangement of cells on any particular tissue culture dish at the time of PEG treatment. After fusion with PEG, cells were prepared for incubation with CTLs to determine if target antigens were distinguishable on the heterokaryon cell surfaces. C3H/He effector T cells, specific for H-2^k/SV40 antigens, were elicited and a ^{51}Cr-release assay was performed as previously described[1] (Fig. 1). The results of the CML assay indicated that CTLs were able specifically to lyse at least some cells in the PEG-treated cell population. The parent cells themselves were not lysed by the effectors as they lacked either SV40 transformation or the H-2^k antigen. Furthermore, the per cent lysis of parent cells which had been subjected to the fusion procedure did not change significantly from the untreated controls. These data indicated that the heterokaryon cells had acquired the target antigen which neither parent by itself possessed and that PEG treatment alone did not cause binding and fusion of effector cells with 'incorrect' target cells.

Numerous reports have indicated that parental cells comprising heterokaryons are capable of inducing various activities in one another[8]. In fact, the SV40 T antigen has been shown to migrate in heterokaryons from the SV40-transformed nucleus to the nucleus of the normal parent[9]. Therefore, to confirm the hypothesis that target antigen formation involved simple mixing of two or more components already present in the transformed cell it was necessary to show that the SV40-transformed parent cells were not directing the non-SV40 cells to alter their 'self-antigens' at the levels of transcription or translation. It was predicted that if the target antigen on an SV40-transformed syngeneic cell was a product of freely moving moieties, then *de*

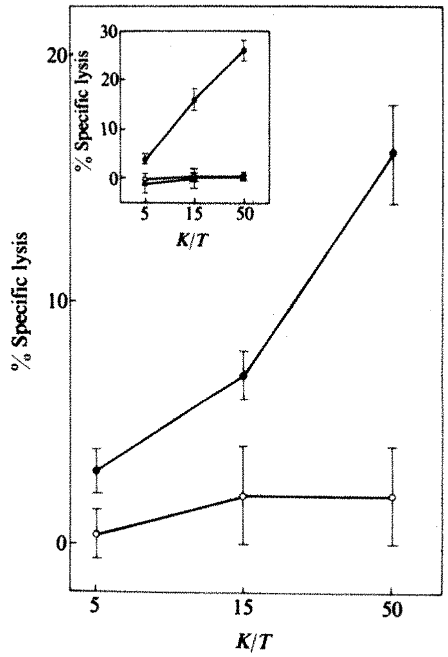

Fig. 1 CML of heterokaryon target cells by anti-H-2^k/SV40 restricted effectors at various killer to target ratios. Target cells are mixtures of H-2^k and H-2^b/SV40 cells fused with PEG (●), and H-2^K and H-2^b/SV40 cells not subjected to PEG treatment (○). All cells (including controls) were labelled at the time of mixing with 100 μCi ^{51}Cr per 100 mm dish. Cells were collected 2 h after PEG fusion with trypsin and used as targets in the ^{51}Cr-release CML assay (see Table 1). Insert: lysis of control targets by anti-H-2^k/SV40 effectors: H-2^k/SV40 (●): H-2^k (○); and H-2^b/SV40 (▲).

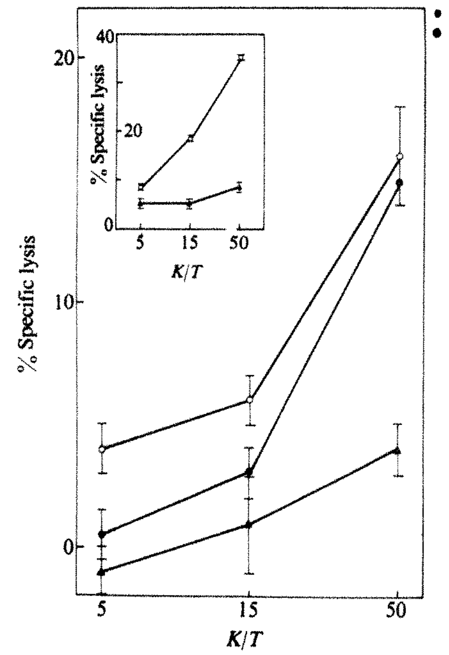

Fig. 2 Lack of a requirement for *de novo* protein synthesis in target antigen formation on heterokaryon target cells. Immediately after PEG fusion cells were incubated either in the absence (DME 10 − cyclo) or presence of 25 mM cycloheximide (DME 10 + cyclo). After 2 h cells were collected and aliquots removed for treatment with papain. Cells (2.5×10^6) in 0.5 ml were added to a solution containing 0.01 M cysteine, 50 μg DNase and 5 mg of papain. The volume was brought to 5 ml with DME 10 (with or without cycloheximide) and the tubes were incubated at 37 °C, 5% CO_2 and 95% air. After 60 min cells were centrifuged at 100*g* for 10 min, washed three times with DME 10 ± cyclo and prepared for use in the ^{51}Cr-release assay. H-2^k and H-2^b/SV40 cells were fused and treated with cycloheximide (●); papain (○); or cycloheximide and papain (▲). Effector cells in the CML assay were H-2^k/SV40 restricted. Insert: H-2^k/SV40 cells were treated with papain (○), or cycloheximide and papain (▲) along with the experimentals.

novo protein synthesis should not be required for target antigen formation in the heterokaryon cell. To address this point cycloheximide, an inhibitor of translation, was added to the incubation medium immediately after fusion with PEG (Fig. 2). The efficiency with which cycloheximide inhibited protein synthesis necessary for target antigen formation was tested by treating target cells with papain before the ^{51}Cr-release assay. Treatment with papain rendered the target cells refractile to lysis by the effectors probably by cleaving off part or all of the target antigen from the surface of the cell. Normally the SV40 target cell will synthesise more antigen and become susceptible to lysis by about 2 h (data not shown). Addition of cycloheximide effectively inhibited the reappearance of the target antigen following papain treatment both on the control targets (see insert Fig. 2) and on the heterokaryon cell population (Fig. 2). Although cycloheximide efficiently inhibited resynthesis of target antigens from the papain-treated cells, it had little effect on the 'manufacture' of target antigens on heterokaryons. Lysis of heterokaryon cell populations with or without cycloheximide by the anti-H-2^k/SV40 effectors was very similar.

These results are most consistent with the hypothesis that mixing of virus-induced and H-2 moieties is sufficient for target antigen formation in SV40-transformed cells. The data do not support any hypothesis in which the target antigen is produced before or during translation. Our results are similar to those seen by Sugamura *et al.* with T-cell mediated lysis of syngeneic Sendai virus-infected cells, where fusion of inactivated virus into the cell membrane was also sufficient to produce the target antigen[10].

Although these findings indicate that an 'altered-self' antigen is not produced by virus-directed transcriptional or translational modification of H-2 antigens, they do not rule out post-translational alterations. For example, the SV40-coded nuclear T antigen has been reported to have protein kinase activity[11], so that phosphorylation of H-2 molecules could produce the T-cell target antigen. Alternatively, T-cell recognition could require the formation of complexes between H-2 antigens and a virus-coded moiety on the cell surface. Finally, it remains possible that no interaction between virus and H-2 molecules is required, but that recognition is mediated via two separate receptors on the T cell for which only the proximity of molecules on the target cell surface is necessary.

We thank Drs David Searls and Michael Edidin for help with the cell fusion method and Ms Janice Kerber for help in preparing the manuscript. This investigation was supported by research grant CA-26476 and training grant T32-CA-09058 from the NCI, DHEW and by grant IM-136 from the American Cancer Institute.

Chromosome abnormalities of leukaemic B lymphocytes in chronic lymphocytic leukaemia

John N. Hurley, Shu Man Fu & Henry G. Kunkel

The Rockefeller University, New York, New York 10021

R. S. K. Chaganti & James German

The New York Blood Center and Memorial Sloan-Kettering Cancer Center, New York, New York 10021

Chromosome analyses have revealed abnormalities in many cases of lymphoma, non-lymphocytic leukaemia and acute lymphoblastic leukaemia. Most studies on chronic lymphocytic leukaemia (CCL), however, have shown normal karyotypes[1–4] although chromosomal abnormalities have been reported[5,6]. In most of these studies specific surface marker analyses on leukaemic lymphocytes have not been carried out. It has been difficult to establish whether the metaphases seen in the majority of the CLL studies were from normal or from leukaemic cells. Recently, in one of our laboratories special interest has centred on cases of CLL with monoclonal serum protein bands; in two such cases with immunoglobulin M (IgM) bands, it was demonstrated with idiotypic antisera against the serum IgM band that the leukaemic lymphocytes were the precursors of plasma cells responsible for the monoclonal serum IgM[7,8]. In addition, the leukaemic lymphocytes of these patients could be stimulated *in vitro* to divide and to differentiate to plasma cells[8]. Epstein-Barr virus (EBV)-transformed lymphoblastoid cell lines were obtained from the two patients. With the idiotypic determinants as leukaemia specific markers, certain of these lines were shown to be derived from leukaemic cells[9]. Thus, rapidly proliferating populations of cells, which could be identified with certainty as being of CLL origin, were available for chromosome analysis. In the present study, conventional G- and Q-banding techniques for karyotypic analysis were carried out on the leukaemic lymphocytes induced to divide *in vitro* and on the cells of the leukaemic lymphoblastoid lines. Aneuploid karyotypes were found in the leukaemic B cells of both patients.

In the first case, Se, multiple cell lines were obtained[9] before the patient received chemotherapy or radiation. One of these lines, SeD, derived from splenic tissue, was shown to be derived

0028-0836/80/010076—03$01.00

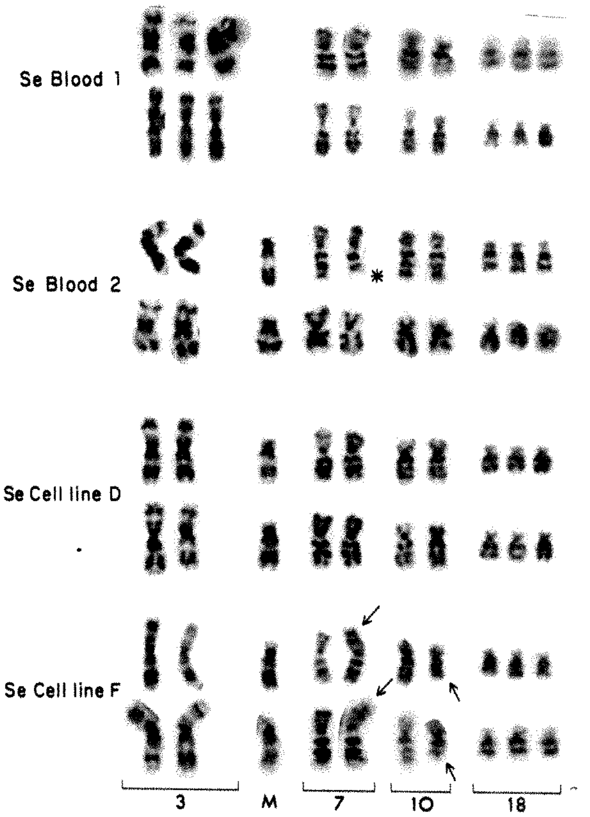

Fig. 1 Partial karyotypes showing all the abnormalities detected in the leukaemic cells from patient Se (G-banding). Cell line SeD, which had been derived from spleen before treatment, contains an extra chromosome 18 and an extra structurally abnormal chromosome (M) derived mainly from a chromosome 3. Cell line SeF, derived from peripheral blood after chemotherapy, contains both of the abnormalities found in cell line SeD plus an apparently balanced translocation between a no. 7 and a no. 10 (arrows). Leukaemic cells circulating in the blood (post-treatment) had two chromosome complements: one (Blood 2) was like that of cell line SeD which had been derived 30 months before the blood samples were taken, the other (Blood 1) differed from that of SeD only in having an extra intact no. 3 instead of the no. 3-derived marker chromosome (M). The terminal dark band missing from the long arm of one no. 7 chromosome of Blood 2 (*) was not found to be absent from any other cell; its significance is unknown.

from her leukaemic lymphocytes[9]. The modal number of chromosomes in line SeD was 48. This line's chromosome complement consisted of 46 apparently normal chromosomes, an extra no. 18 and an extra marker chromosome, M, which differs from any normal human chromosome as a result of structural rearrangement. The banding pattern of M suggests that it consists of the entire long arm, the centromere and a tiny segment of the short arm of a no. 3 to which a minute piece of some other chromosome has been translocated. The karyotype of cell line SeD can be described as 48, XX, +18, +M (Fig. 1). The extra chromosome 18 is apparently normal. Cell line SeF, a second leukaemic cell line, was derived from the patient's blood 2 yr after the establishment of line SeD and after chemotherapy with chlorambucil had been given. The leukaemic cell origin of this line was demonstrated by idiotypic analysis in a similar manner to that for SeD[9]. As in SeD, a modal chromosome number of 48 was observed in SeF, but an additional chromosome abnormality was present, a translocation between the long arms of a no. 7 and a no. 10. The karyotype of line SeF can be described as 48, XX, −7, −10, +18, +M, +t (7p; 10q) (Fig. 1). SeAl, one of the several lymphoblastoid cell lines from the same patient, derived from her non-leukaemic B cells[9], had a normal 46, XX karyotype.

In the previous studies[8], leukaemic B cells from patient Se matured to plasma cells *in vitro* in the presence of pokeweed mitogen (PWM) and autologous T cells. Of the plasma cells identifiable with the anti-idiotypic serum to the monoclonal IgM serum band (IgM Se), 15% showed ^{3}H-thymidine incorporation by autoradiography. The majority of the dividing cells in the non-T population stained with anti-idiotypic antiserum and thus were of leukaemic origin[8]. To obtain metaphases from dividing leukaemic B cells, Se peripheral blood lymphocytes were stimulated with PWM for 3 d, after which T cells were separated from non-T cells by the sheep erythrocyte rosette method and the chromosome complements in each fraction analysed. All the metaphases obtained in the T-cell fraction had a normal karyotype, 46, XX. However, in the non-T-cell preparation, a bimodal distribution of chromosome numbers was observed, with the major mode having 48 chromosomes and the minor 46 chromosomes (Table 1). Of 50 G-banded cells, 24 had the complement 48, XX, +3, +18 and 5 had 48, XX, +18, +M (Fig. 1). A substantial number of the metaphases had a normal karyotype, which was probably from contaminating dividing normal cells. In addition, a normal karyotype was found in metaphases obtained directly from Se's freshly aspirated bone marrow cells as well as her peripheral blood lymphocytes stimulated with phytohaemagglutinin (PHA).

The chromosome abnormalities observed in the cell lines and the *in vitro* induced dividing peripheral blood leukaemic lymphocytes from patient Se are summarised in Fig. 1. Trisomy 3 and trisomy 18 seem to represent the earliest detected alterations in the patient's leukaemic clone. As the karyotype of the clone evolved, M replaced a chromosome 3 and, later, translocation between chromosomes 7 and 10 occurred. In chronic myelogenous leukaemia entering the blastic phase, sequential alterations of the karyotype of this type have been found to be superimposed on the Ph^1 translocation[10]. In CLL patient Se, correlation between the observed sequential alteration and altered clinical activity was not apparent.

Similar cytological studies were carried out on selected cell lines[9] derived from the peripheral blood of CLL patient Ei after she had been treated with chlorambucil and prednisone. An idiotypic antiserum against the IgM Ei serum protein demonstrated that cell lines Ei 25, Ei 28 and Ei 81 were derived from her leukaemic lymphocytes[9]. All three leukaemic lines analysed had a modal chromosome number of 47, with the karyotype 47, XX, +12, and were, therefore, trisomic for what seems to be a normal chromosome 12. The lymphoblastoid lines Ei 151 and Ei 152 were shown by idiotypic analysis to be derived from non-leukaemic B cells, and the karyotypes of these two non-leukaemic lines were normal (46, XX). The finding of trisomy 12 in all three independently derived leukaemic cell lines and its absence in the two normal lines suggest that the chromosome abnormality is not a result of changes produced by chemotherapy or EBV transformation and cell culture.

Simultaneous trisomy of chromosomes 3 and 18 has been described in the non-Hodgkin lymphomas[5], although a structural rearrangement of chromosome 14 (14q+) is the most frequent abnormality[1,2,5]. A 14q+ chromosome has also been found in two patients with chronic T-cell leukaemia[6], in two CLL patients with undetermined cell types[5] and in a patient with a B-cell CLL[11]. Trisomy 12 has been observed in at least two patients with hairy cell leukaemia[12]. In the present studies, the finding of trisomies 3 and 18 in patient Se and trisomy 12 in patient Ei suggest similar chromosome abnormalities in cases of CLL, malignant lymphoma and hairy cell leukaemia. None of

Table 1 Chromosome numbers in pokeweed mitogen-stimulated peripheral blood mononuclear cells from patient Se after depletion of T cells

	Chromosome nos per cell						No. of cells examined
	≤44	45	46	47	48	49

Q-banding	0	0	6	4	20	0	30
Total	1	6	17	6	49	1	80

these chromosome abnormalities is known to be associated specifically with a particular type of lymphoproliferative disorder.

Thus, the leukaemic cells of both patients with CLL analysed in this study showed chromosome abnormalities. These were demonstrated in the *in vitro* stimulated cells from patient Se and the virus-transformed cell lines derived from both patients. The finding of normal karyotypes in the metaphases obtained from fresh bone marrow cells, PHA-stimulated cells and PWM-stimulated T cells in patient Se emphasises the difficulties inherent in cytogenetic studies of CLL. Without the idiotypic determinants as specific markers of the leukaemic cells, it would have been difficult to identify the leukaemic cells and demonstrate the associated chromosome abnormalities. The trisomy 3 and 18 in one patient and the trisomy 12 in the other are among the first well documented karyotypic abnormalities in chronic lymphocytic leukaemia of the common B-cell type. The fact that both patients studied showed abnormalities suggests that they occur at high frequency in cases of CLL but the exact incidence can be determined only when methods for identifying and inducing division of the leukaemic cells have been developed.

We thank Mr Ralph Ehrenpreis for assistance in the cytogenetic studies and Ms Linda Light for secretarial help. This study was supported by USPHS grants RR 102, CA 24338, AI 10811, HD 04134 and HL 09011, and by a grant from the American Cancer Society. S.M.F. is a scholar of the Leukaemia Society of America.

Inability of the C3a anaphylatoxin to promote cellular lysis

Michael G. Goodman & William O. Weigle

Department of Immunopathology, Scripps Clinic and Research Foundation

Tony E. Hugli

Department of Molecular Immunology, Scripps Clinic and Research Foundation, La Jolla, California 92037

Investigation of the biological effects of the cleavage product, C3a, derived from the third component of complement has generally focused on the effects it exerts as an anaphylatoxin[1], that is, smooth muscle contraction[2] and histamine release from mast cells[3,4] and basophils[5,6]. Therefore, reports that C3a exerts cytoxic effects on various cell types [7–9], and exhibits concentration-dependent specificity for malignant cells[9], excited great interest. The cytolytic activity mediated by macrophages which were activated *in vitro* may be attributed to their ability to generate C3a[10]. The far-reaching implications of such a cytolytic role for C3a led us to pursue these observations further. We report here that we have been unable to duplicate the results reported by Ferluga *et al.*[9]. On the contrary, we find that C3a actually reduces spontaneous release of label below normal background levels.

Human, porcine and rat C3a were purified according to established procedures[11,12]. Purity of the final products was assessed by polyacrylamide gel (*p*H 4.5) and cellulose acetate strip (*p*H 8.5) electrophoresis. All preparations were judged homogeneous based on the criteria of electrophoretic behaviour and a distinct amino acid composition. Functional activities of the anaphylatoxins were determined by the guinea pig ileal assay and from the ability to enhance vascular permeability in guinea pig skin[1]. Human $C3a_{desArg}$ was prepared according to the procedure of Hugli *et al.*[11] except that the serum carboxypeptidase B inhibitor, 6-aminohexanoic acid, was omitted during the complement activation step.

Table 1 Effect of human C3a on murine target cells

Expt 1

C3a concentration ($\mu g\ ml^{-1}$)	P-815 Cells ^{51}Cr release (c.p.m. per culture)	P-815 Cells % Specific release
0	190 ± 29	0
1	159 ± 19	−5
3	152 ± 22	−6
10	174 ± 5	−2
30	167 ± 3	−3
100	162 ± 18	−4

Expt 2

C3a concentration ($\mu g\ ml^{-1}$)	P-815 cells ^{51}Cr release (c.p.m. per culture)	P-815 cells % Specific release	Spleen cells ^{51}Cr release (c.p.m. per culture)	Spleen cells % Specific release
0	768 ± 46	0	1,494 ± 59	0
1	752 ± 86	−1	1,203 ± 101	−30
3	738 ± 41	−1	1,112 ± 123	−39
10	715 ± 19	−2	1,051 ± 54	−45
30	661 ± 57	−5	1,007 ± 87	−49
100	636 ± 17	−6	727 ± 29	−78

In expt 1 a total of 5×10^6 P-815 cells were labelled with ^{51}Cr-labelled sodium chromate in 1 ml medium and incubated at 37 °C for 1 h. Total release was 868 ± 0 c.p.m. ^{51}Cr release was assayed after 6 h of incubation. Each culture contained 3.5×10^4 target cells + the concentration of C3a indicated. In expt 2, 5×10^6 P-815 or spleen cells were labelled with ^{51}Cr-labelled sodium chromate in 0.3 ml medium and incubated at 37 °C for 1 h. Total release was 3,131 ± 89 c.p.m. for P-815 cells and 2,480 ± 57 c.p.m. for spleen cells. The per cent specific release of label from target cells attributable to the action of C3a was calculated according to the formula:

$$\frac{(\text{Experimental release} - \text{spontaneous release})}{(\text{Total release} - \text{spontaneous release})} \times 100$$

Total release was evaluated by adding a drop of 10% SDS to cultures containing target cells only. Data are presented as the arithmetic mean of triplicate cultures ± s.e.

Dissociated suspensions of murine spleen cells were prepared and cultured in RPMI-1640 based medium as detailed elsewhere[13]. This medium was supplemented with bovine serum albumin (BSA) or heat-inactivated fetal calf serum (FCS) as indicated. FCS was tested for and found deficient in carboxypeptidase B activity. The $H\text{-}2^d$ mastocytoma P-815 and the $H\text{-}2^b$ lymphoma EL-4 were maintained *in vivo* in DBA/2 and C57BL/6J mice, respectively. Target cells were labelled according to several different protocols. For the first protocol, 5×10^6 viable target cells were suspended in 1 ml of medium together with 100 μCi of ^{51}Cr-sodium chromate, and incubated for 1 h at 37 °C. Target cells were washed four times and resuspended at a density of 3.5×10^5 per ml in medium containing 0.1% crystallised BSA. In other experiments the same labelling protocol was followed except that the total volume of incubate was 0.3 ml. The use of this latter protocol resulted in a higher degree of labelling per cell. Several other labelling techniques were tested to optimise the amount of label taken up per

0028–0836/80/010078—03$01.00

Table 2 Effect of C3a from different species on P-815 target cells

^{3}H-TdR release was assayed after 6 h of incubation. Each culture contained 5×10^{4} target cells plus the concentration of C3a indicated. Total release was 59,427 ± 4,386 c.p.m. per culture. Data are presented as the arithmetic mean of five replicate cultures ± standard error. For the human C3a$_{\text{des Arg}}$ experiment ^{3}H-TdR release was also assayed after 6 h of incubation and each culture contained 5×10^{4} target cells. The concentration of C3a$_{\text{des Arg}}$ is indicated and total release was 23,010 ± 530 c.p.m. per culture. Release in the cultures with 100 μg ml^{-1} of intact C3a instead of C3a$_{\text{des Arg}}$ was 195 ± 12 c.p.m. per culture (−0.8% specific release).

cell. The most satisfactory protocol on this basis, was that described by Bloom *et al*[14]. Briefly, target cells were incubated in the same RPMI-1640 based medium used previously with the exception that BSA was omitted and 10% heat-inactivated FCS as well as 5×10^{-5}M 2-mercaptoethanol were added. 10^{7} target cells were incubated in 60-mm Petri dishes with 5 μCi ml^{-1} of ^{3}H-TdR in a volume of 10 ml. Cultures were incubated for 18–24 h, washed four times, resuspended to 10^{6} cells per ml in serum-free medium and used directly.

^{51}Cr-labelled target cells were assayed according to the procedure of Ferluga *et al.*[9]. Briefly, 3.5×10^{4} target cells in a volume of 0.1 ml medium were combined with various concentrations of C3a (in 20 μl of gelatin–saline) in 12 × 75-mm round bottomed tubes and incubated in an atmosphere of 5% CO_2 at 37 °C for the time indicated. At that point, 1 ml of 5% FCS-containing medium was added per tube, samples were mixed gently, centrifuged, and 0.5 ml of the supernatant was removed and counted in a Searle 1195 automatic gamma counter. Target cells labelled with ^{3}H-TdR were assayed as follows: 5×10^{4} target cells in a volume of 50 μl were added to microculture wells (Falcon Plastics no. 3040, 3041) together with a 2× concentration of human C3a in a volume of 50 μl of gelatin–saline. Cells were incubated for 6 h unless otherwise stated, at which point the assay was terminated by adding 100 μl of medium containing 10% FCS to each well. The microculture plate was then centrifuged and 100 μl per culture was harvested into scintillation vials containing 3 ml of Aquasol. Samples were counted in a Beckman LS-230 liquid scintillation counter.

The data presented in Table 1 are results from experiments in which variable concentrations of human C3a were incubated with two different types of radiolabelled target cells. Significant release of label from the target cells, an event that would indicate lysis initiated by C3a, failed to occur. Although these experiments were performed repeatedly and the methodology specified by Ferluga *et al.*[9] was adhered to fastidiously, lysis was never observed. This was true of ^{51}Cr-labelled P-815 target cells, the cell type reported to be the most readily lysed, as well as EL-4 and normal murine splenic lymphocytes. The susceptibility of these target cells to lysis, as judged by their release of the ^{51}Cr label, was previously established by incubating the cells with allogeneic cytotoxic T lymphocytes which had been specifically educated *in vivo*. The range of C3a concentrations tested was precisely that which has been previously reported to produce lytic activity against labelled target cells[9]. The assays presented in Table 1 were performed after 6 h of incubation, as specified by Ferluga *et al.*[9]. However, in other experiments (data not shown) the kinetic profile (between 2 and 24 h of culture) was examined. The results of these experiments demonstrated that lysis could not be induced regardless of the duration of the incubation. Viability studies showed no differences in cell number or in per cent viability between control and C3a-incubated cultures (data not shown).

As our next approach, highly purified C3a preparations of human, rat, and porcine origin were studied to determine whether the inability of human C3a preparations to lyse target tumour cells might be simply a species limitation. The results of experiments using ^{3}H-TdR-labelled P-815 mastocytoma target cells are presented in Table 2. Here again, the actual counts released per culture, as well as the per cent specific release, are presented as a function of the concentration of C3a used in culture. Once more it is apparent that there is no lysis induced by C3a in excess of the background spontaneous release regardless of its species derivation, over the entire range of concentrations examined in Table 1. Although guinea pig C3a was used in the studies of Ferluga *et al.*[9], the use of C3a from a variety of species (Table 2) makes it unlikely that cytolysis is peculiar to the guinea pig molecule especially since the target cells were xenogeneic. Moreover, it appears that if any activity can be ascribed to the presence of C3a in culture, that activity would be a diminution of the spontaneous release of radioactive label from target cells. The fact that biology inactive C3a$_{\text{des Arg}}$ exhibits the same effect as intact C3a on spontaneous release argues that this phenomenon is not an anaphylatoxin-specific effect.

In other studies, the effect of C3a on isologous target cells was studied. Human lymphoblasts, generated from PBL (activated by staphylococcal protein A under optimal mitogenic conditions for 6 d) were incubated with concentrations of human C3a

Table 3 Effect of polyamines on spontaneous lysis of murine tumour cells

	Human C3a		Spermidine	
Concentration (μg ml^{-1})	^{3}H-TdR release (c.p.m. per culture)	% Specific release	^{51}Cr release (c.p.m. per culture)	% Specific release
0	5,826 ± 440	0	5,826 ± 440	0
1	3,524 ± 90	−4.5	3,599 ± 173	−4.3
3	3,702 ± 124	−4.1	2,829 ± 223	−5.8
10	3,300 ± 34	−4.9	1,735 ± 128	−7.9
100	3,143 ± 97	−5.2	589 ± 34	−10.2

^{3}H-TdR release was assayed after 6 h of incubation. Each culture contained 5×10^{4} P-815 target cells plus the concentration of C3a or spermidine indicated. Total release was 57,328 ± 5,553 c.p.m. per culture in these experiments.

ranging from 1 to 200 μg ml^{-1}. The results of these experiments demonstrated that purified human C3a was incapable of mediating the release of label from human lymphoblastoid target cells.

Theoretically C3a should be able to interact with cells either by high or low affinity receptor–ligand binding, or by low affinity nonspecific interactions (such as salt bridging and hydrogen bonding). In a recent paper, Glovsky and colleagues[6] studied the binding of purified human C3a to human eosinophils, neutrophils, basophils, monocytes and lymphocytes. Of particular interest was their observation that virtually no detectable binding of human C3a to peripheral blood lymphocytes occurred. In the light of these findings, it is difficult to comprehend the rational basis for specific lysis of human lymphoblasts by C3a observed by Ferluga and coworkers[9]. One would have to postulate a nonspecific or low affinity mechanism to account for such findings since high affinity binding of C3a to a specific cellular receptor is apparently ruled out.

On the contrary, diminution of spontaneous cytolysis by C3a was conceptualised as a nonspecific effect of polycations. To evaluate this possibility salmon spermidine, a polyamine of comparable size to C3a, was evaluated for its influence on the spontaneous lysis of labelled target cells. Table 3 demonstrates that increasing the concentration of salmon spermidine does in fact produce a diminution in the spontaneous release of cellular label. The effect of spermidine in our case is not likely to be due to inhibitory metabolites produced by polyamine oxidase contained in FCS acting on spermidine as a substrate[15]. It has been demonstrated that inhibitory effects attributable to such metabolites are reversed by washing, and in the present studies cells were washed four times before addition of spermidine in serum-free medium. Moreover, the same effects of polycations were observed when target cells were labelled in the absence of serum. The decrease in spontaneous release is interpreted as indicating that polyamines, similar in size and charge to C3a, are capable of exerting either direct or indirect nonspecific stabilising effects on the cell. This same conclusion has been independently corroborated by experiments in which human C3a was incubated with human peripheral blood neutrophils. Under those circumstances, the spontaneous release of lactate dehydrogenase (LDH) decreased concordantly with increasing concentrations of C3a (D. E. Chenoweth, personal communication).

We thus find no evidence to support the contention that C3a plays a significant cytolytic role in the host defense mechanisms against neoplasia.

We thank Miss Anne Zumbrun for her technical assistance and Miss Holly Wimer for secretarial work in the preparation of the manuscript. This is publication number 1857 from the Research Institute of Scripps Clinic, and was supported by NIH research grants A1 700070, HL 16411 and AI 15284.

Prostaglandin synthesis in different phases of phagocytosis in lung macrophages

Wei Hsueh, F. Gonzalez-Crussi & Eric Hanneman

Department of Pathology of The Children's Memorial Hospital, Northwestern University Medical School, Chicago, Illinois 60614

Macrophages have a central role in bodily defence and inflammatory responses. Prostaglandins (PGs), mediators of inflammation[1], are secreted by macrophages during phagocytosis. PGE-like activity was first demonstrated in macrophage-rich peritoneal exudate cell preparations from guinea pigs[2,3]; later, other kinds of PGs were also found to be released by mouse peritoneal macrophages in response to inflammatory stimuli[4–6]. We have shown that rabbit alveolar macrophages also produce various PGs in response to phagocytic stimuli like zymosan and heat-killed bacteria[7,8]; however, it was not known precisely which cellular event is associated with PG production. Traditionally, the phagocytic process is considered in three stages: (1) attachment of the particle to the cell membrane; (2) interiorisation (phagocytosis); and (3) fusion of the phagocytic vesicle with intracellular lysosomes (digestion). We show here that PG secretion in response to phagocytic stimuli by macrophages is independent of the first stage, but dependent on engulfment of the particle. Moreover, PG production does not appear to be associated with the process of engulfment *per se*, but with some event following internalisation.

To assess the release of PGs, we prelabelled the culture rabbit alveolar cells (>90% macrophages) with ^{14}C-arachidonic acid (Amersham Searle), as previously described[7]. Analysis of the cell lipids showed that approximately 40–50% of the radioactive arachidonic acid was incorporated into the cell lipids after 1 h of incubation. Most of the radioactivity (68%) resided in phospholipid (41±2% phosphatidyl choline, 17±3% phosphatidyl ethanolamine, and 10±2% phosphatidyl serine and phosphatidyl inositol) ($n = 10$). A small amount (9±2%) was also incorporated into the neutral lipids; only 1–2% of the radioactivity in the cells remained in free fatty acid form. The pattern of incorporation was similar to our previous observation[7].

It has been also shown that concanavalin A (Con A)-treated red blood cells (RBCs) attach to the macrophages, but are not engulfed[9]. We took advantage of this model to study the attachment phase of phagocytosis. As shown in Fig. 1*a*, the Con A-treated RBCs bound to the alveolar macrophages to form rosettes, but none was engulfed at the end of the incubation period (3 h). The PG production of these macrophages was no different from that of the unstimulated group (Fig. 2*a*). However, when anti-rabbit RBC antiserum was added to the culture media together with rabbit RBCs, the latter were rapidly interiorised (Fig. 1*b*). Accordingly, the PG secretion showed a 60% increase compared with the control group (Fig. 2*a*). Neither RBCs nor antiserum alone caused any increase of PG synthesis by macrophages. Thus, the PG release by macrophages during RBC phagocytosis is not dependent on attachment of the RBCs to the macrophage membrane, but depends on the engulfment of the RBCs by these phagocytic cells. This result differs from observations of Goldstein *et al.*[10] in other phagocytic cells such as granulocytes. These cells, once rendered incapable of ingesting particles by treatment with cytochalasin B, generated comparable amounts of thromboxane B_2 to untreated, normal cells.

PG release following RBC phagocytosis by rabbit alveolar macrophages was predominantly PGE_2 (38±4% of total PG released), although PGD_2 (14±2%), $PGF_{2}\alpha$ (25±2%), and

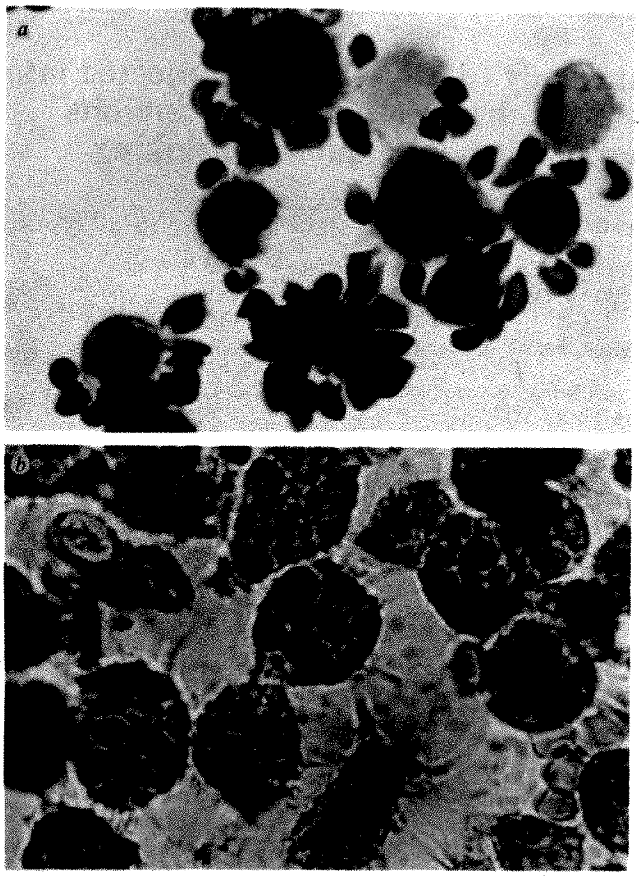

Fig. 1 *a*, Attachment of Con A-treated RBCs to cultured alveolar macrophages. RBCs were collected, washed twice with phosphate-buffered saline (PBS) (*p*H 7.4), resuspended in PBS containing 0.7 μg ml^{-1} Concanavalin A (Sigma), and incubated at 37 °C for 30 min. The RBCs were then washed twice with PBS and 1×10^7 RBCs were added to cultured alveolar macrophages (5×10^6 cells ml^{-1} on each plate). At the end of experimental period, the cells were fixed *in situ* with 10% formalin and stained with haematoxylin and eosin (H and E). *b*, Engulfment of RBCs by cultured alveolar macrophages. The anti-rabbit RBC antiserum was prepared from mice by a modified method of Rabinovitch[11]. A group of 10 mice were injected twice intravenously with 0.2 ml of 10% rabbit RBCs suspended in PBS. The interval between injections was 30 d, and the mouse serum was collected 6 d after the second injection. Fresh rabbit RBCs were collected and washed twice with PBS and 1×10^7 cells were added to alveolar macrophages (5×10^6 cells per plate) in the presence of anti-rabbit RBC antiserum. The cells were fixed *in situ* with 10% formalin at the end of experimental period and stained with H and E stain.

6-keto PGF$_{1}\alpha$ (22±3%) ($n=5$) were also detected in the medium, with a profile very similar to that of zymosan-stimulated alveolar macrophages[7,8].

Our previous work also showed that cytochalasin B, an inhibitor of phagocytosis, when given to zymosan-treated macrophages, increased PG production instead of inhibiting it[7]. In the absence of zymosan, however, cytochalasin B exhibited no effect on PG production[7]. One possible explanation for this paradoxical phenomenon is that PGs are produced during particle–membrane interaction, and that by inhibiting engulfment of the particles, cytochalasin B prolongs the attachment phase, that is, the particle–membrane interaction, thus enhancing PG production. If this hypothesis obtained, we should be able to see a stimulatory effect of cytochalasin B on PG production, when Con A-treated RBCs were used as a stimulus for particle attachment. As shown in Fig. 2*a*, this hypothesis is clearly false. There was no increase of PG secretion by macrophages when cytochalasin B was added to Con A-treated RBCs. However, when RBCs were engulfed in the presence of anti-RBC antiserum, a facilitatory effect of cytochalasin B on PG secretion was clearly demonstrated. This increment was demonstrable at both doses that inhibited phagocytosis (2 μg ml^{-1} and below 0.5 μg ml^{-1}). Therefore, we have shown that: (1) the PG stimulating effect of cytochalasin B was not a result of inhibition of phagocytosis or prolongation of particle–membrane interaction; and (2) the stimulatory effect of cytochalasin B was dependent on the interiorisation of the phagocytosed particles.

Finally, we investigated the relationship between particle engulfment and PG secretion. Zymosan was used instead of

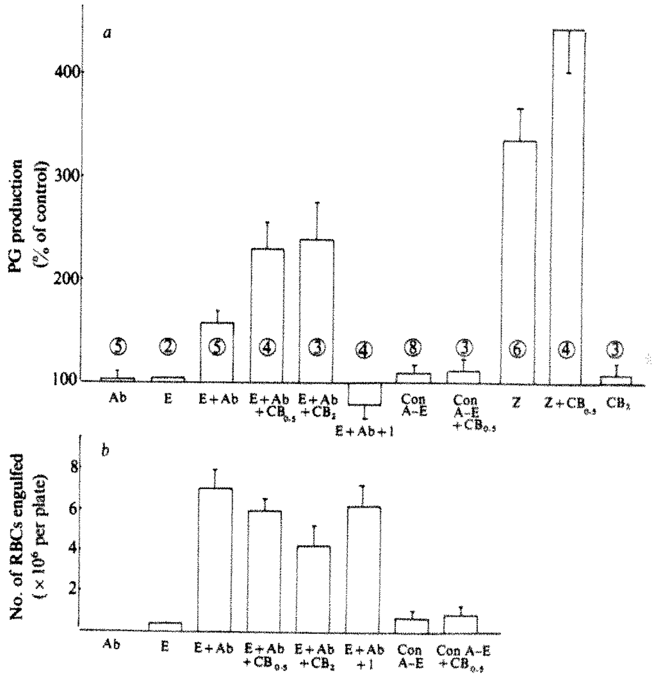

Fig. 2 *a*, ^{14}C-PG production by rabbit alveolar macrophages in response to different stimuli. Rabbit alveolar macrophages were collected as previously described[7] (5×10^6 cells ml^{-1} on each plate). After overnight incubation, the cells were changed to serum-free Dulbecco's modified Eagle's medium (DMEM). ^{14}C-arachidonic acid (specific activity 55 mCi mmol^{-1}, Amersham Searle) was added to the cultures as the Na salt at a concentration of 1×10^6 c.p.m. ml^{-1}. The cultures were incubated for 1 h to label the cell lipids. Cells were washed twice with DMEM, different stimuli were added to the cells and they were incubated for 2.5 h in DMEM containing penicillin (100 μg ml^{-1}), and streptomycin (100 μg ml^{-1}). At the end of the experimental period, the medium was collected, acidified to *p*H 3.5 with formic acid, extracted twice with an equal volume of ethyl acetate, dried and applied to silica gel G plates. The solvent system used for separation of PGs was the organic phase from ethyl acetate : water : iso-octane : acetic acid, 110:100:50:20 (ref. 12). Zones corresponding to various PG standards (provided by Dr John Pike, Upjohn, Kalamazoo) were scraped and counted in a liquid scintillation counter. The total PG release (sum of 6-keto PGF$_{1}\alpha$ + PGF$_{2}\alpha$ + PGE$_2$ + PGD$_2$) was calculated and expressed as the percentage of the control value (unstimulated cells). E, PBS-washed rabbit erythrocytes (1×10^7 cells per plate); Ab, anti-rabbit RBC antiserum (25 μl ml^{-1}); CB$_{0.5}$, cytochalasin B (0.5 μg ml^{-1}); CB$_2$, cytochalasin B (2 μg ml^{-1}); Con A-E, ConA (0.7 μg ml^{-1}) treated RBCs (1×10^7 cells per plate); Z, zymosan (1 mg ml^{-1}); I, indomethacin (2 μg ml^{-1}). The encircled numbers indicate the number of experiments performed (mean±SEM indicated). *b*, Intracellular haemoglobin (Hb) content of macrophages. At the end of the experimental period (2.5 h), the medium was removed and NH$_4$Cl in saline (8.3 mg ml^{-1}) was added to cells to lyse the extracellular RBCs. The medium was again removed, the macrophages were scraped off to a test tube, and Hb content was determined by the cyanmethaemoglobin method[13]. A series of standards of different concentrations of RBCs were used and the Hb content in cells were expressed as number of RBCs in each dish of macrophages (5×10^6 cells ml^{-1} on each plate). (Mean±s.e.m. indicated.)

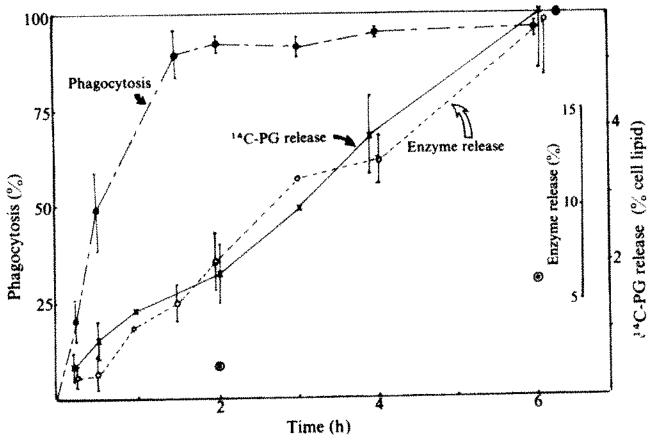

Fig. 3 Time course of phagocytosis of zymosan, lysosomal enzyme release, and PG production by alveolar macrophages. Zymosan was added at time zero, and media were collected at different time intervals for analysis of acid phosphatase activity and PG production. Cells were fixed with 75% alcohol and stained with PAS reaction and the percentage of cells containing two or more zymosan particles (magneta colour by PAS stain) was recorded. The total PG production was determined by radiochemical techniques as described in Fig. 2*a*, and is expressed as percentage of total cell lipid count. The acid phosphatase activity was determined on both medium and cells by a modification of the procedure of Leaback[14]. To determine the intracellular enzyme content, the cells were scraped off the plates into 0.5 ml of 0.1% Triton X-100 in water using a rubber policeman. Aliquots of the cell lysates were diluted 50 times with 0.2 M sodium acetate buffer (*p*H 5). The media were diluted five times with the same buffer. Thirty μl of the diluted medium or cell lysate were added to 70 μl of 4-methylumbelliferyl phosphate (0.05 mg ml^{-1}) in acetate buffer and incubated at 37 °C for 15 min. The enzyme reaction was terminated by adding 1.9 ml of 0.02 M phosphate buffer (*p*H 10.7). The fluorescence was measured in a fluorimeter using a Corning 5860 primary filter and Corning 3387 and 5543 secondary filters. The release of enzyme is expressed as percentage of intracellular acid phosphatase released into the medium (mean + s.e.m., $n = 3$). ×; ^{14}C-PG production; O; percentage of intracellular acid phosphatase released into the medium after zymosan stimulation; ⊚; percentage of intracellular acid phosphatase released into the medium by unstimulated cells; ●, percentage of cells phagocytosing zymosan particles.

RBCs, due to its potent stimulatory effect. As shown in Fig. 3, PG release did not temporally follow the particle engulfment, but exhibited a time lag. Its time course, however, followed closely that of the release of lysosomal enzymes. Furthermore, we have previously shown that cytochalasin B, which increased zymosan-induced release of PGs, also increased that of lysosomal enzymes[7]. Hence, it seems that the release of PGs by alveolar macrophages during phagocytosis is not associated with either the attachment or engulfment phases, but it is concomitant with a much later event, which takes place after the particles have been internalised.

The Thy-1 differentiation antigen on the cell surfaces of mouse and rat thymocytes, lymphocytes[1–4], epidermis[5], developing skeletal muscle[6], and brain[1,3,4] has not yet been assigned a function. In rat and mouse brain, Thy-1 reaches adult levels at about 3 weeks of age from minimal or variably low levels at birth[3,7–9]. *In vitro* studies of fetal or newborn cerebellar neurons have shown that granule cells and some large multipolar cells become Thy-1 positive during culture[10,11]. All dorsal root ganglion neurones in culture express Thy-1[11,12]. The antigen appears to be enriched in synaptosomal fractions[13,14] but Thy-1 has recently been demonstrated on the surface and dendrites of microdissected neurons of adult rat brain[15]. In the brain Thy-1 has been thought to be a neuronal antigen, but some cerebellar astrocytes become Thy-1 positive after prolonged culture[16]. The transient or developed occurrence of the Thy-1 glycoprotein on selected cell surfaces would suggest that it mediates an event associated either with differentiation or with a differentiated function. The recent report by Dulbecco *et al.* that monoclonal hybridoma antibody against Thy-1.1 (aThy-1.1) blocks a differentiation event in culture of a rat mammary carcinoma cell line[17] is, the first demonstration of a functional link between the molecule and a specific developmental process. We consider brain Thy-1 to be a differentiated adult expression, however, and we report here that injecting antibody to Thy-1 antigen into the rat hypothalamns caused selective inhibition of carbamyl choline induced drinking.

Direct chemical stimulation of the perifornical hypothalamus with the α-adrenergic agonist noradrenaline (NA) elicits food intake in sated rats. Stimulation of the cholinergic system at the same site with the acetylcholine analogue carbamyl choline (CC) elicits a sustained drinking response in water-replete rats[18–21]. If the effect of focal antibody treatment is a result of reaction with antigens characteristic of differentiated neuronal function, then a selective potentiation or inhibition of the eating or drinking response to an exogenous transmitter analogue might be anticipated.

Monospecific antibody against Thy-1 antigens (aThy-1) are produced by hydridising mouse myeloma and immune spleen cells, cloning the hybridoma and culturing as a tumour *in vivo*. Hybridoma aThy-1.1 (T32B11) mouse serum, cytotoxic (complement dependent) for AKR mouse thymocytes at a dilution of 1×10^{-5}, and a monoclonal aThy-1.2 (F7D5), cytotoxic for C57BL mouse thymocytes at a dilution of 1×10^{-6} (ref. 22), were kindly supplied by Dr E. A. Clark. Both antisera were included in the study by Dulbecco *et al.*[17] of the effect on the differentiation of mammary cell cultures. Both were tested in our laboratory by indirect immunofluorescence for specific binding to mouse and rat thymocytes. aThy-1.2 bound to C3H cells but not to AKR or rat cells; aThy-1.1 bound to both AKR and rat cells but not to C3H cells, confirming the designated specificity of these antibody preparations. The antibody is not thought to react with carbohydrate determinants since the brain Thy-1 carbohydrate has a different composition from that of the thymocyte Thy-1[23–25].

Twenty-four male Charles River CD rats were implanted with chronic unilateral cannulae aimed at the left perifornical hypothalamus. Following surgery and a 2-week recovery period, the animals were divided into two groups to be tested with NA (6 μg) and physiological saline (PS), or with CC (0.8 μg) and PS to determine baseline eating and drinking responses to chemical stimulation. Drug doses were chosen to produce a vigorous behavioural response. Tests were performed at 4-day intervals in a counterbalanced schedule to detect any sequence effects. Half of the animals received the drug (NA or CC) and half received PS on the first day. In the next test the animals were injected with the other substance. All tests were performed at 4 pm, 2 hours before the onset of the dark period of the light–dark cycle. To initiate behavioural arousal and ensure maximal satiation at the start of the test, each rat was given fresh food and water 30 min before the test period. Immediately after this presatiation period, the animals were removed from their home cages, injected with 1 μl of the test solution (NA, CC or PS) and returned to the cage which contained a fresh amount of premeasured food and water. After 1 hour the remaining food was removed from the cage and, with the spillage, weighed to the nearest 0.1 g to determine food intake. Water intake was read to the nearest 1 ml.

The effect of aThy-1.1 on drug-induced behaviours was determined using the same counterbalancing procedure. Tests were performed at weekly intervals. On test days half of the animals in each group received two 1-μl intrahypothalamic injections of aThy-1.1 at 10 and 10:30 am, 6 hours before the chemical stimulation and consumption test period. For injection into the brain site aThy-1.1 serum was diluted fivefold to 14 μg protein per μl since protein concentrations of 25–35 μg μl^{-1} at this site sometimes gave nonspecific effects on consummatory behaviours.

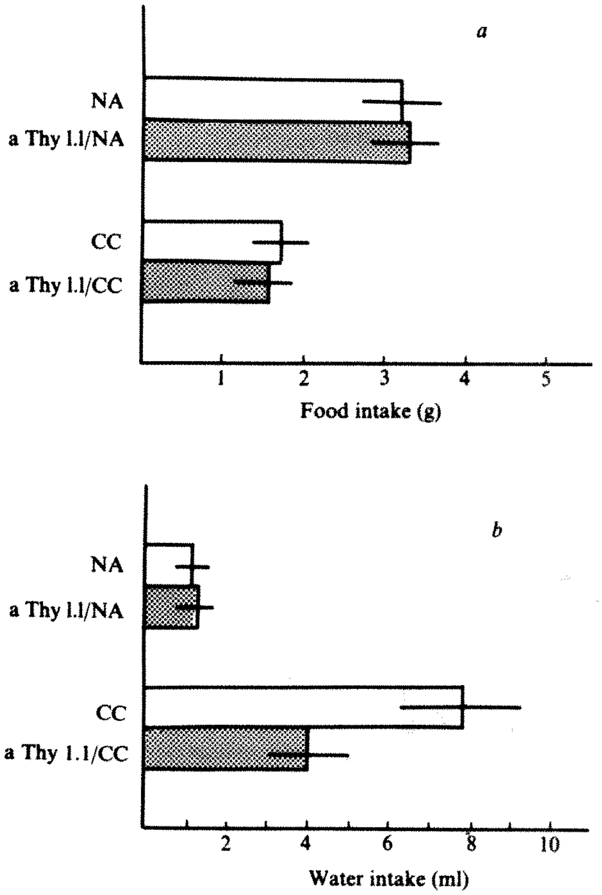

Fig. 1 Drug-induced eating (*a*) and drinking (*b*) modified by intrahypothalamic administration of monoclonal antibody T32B11 to Thy-1.1 antigen (aThy-1.1). Open bars are predetermined drug baseline consumption data. Stippled bars are drug-stimulated consumption data following aThy-1.1 treatment (serum diluted 1/5) administered 6 h before injection of drug into the perifornical hypothalamus. Noradrenaline (NA), 6 μg, and carbamyl choline (CC), 0.8 μg, were administered in 1 μl. ($n = 12$.) Error bars show ±s.e.m.

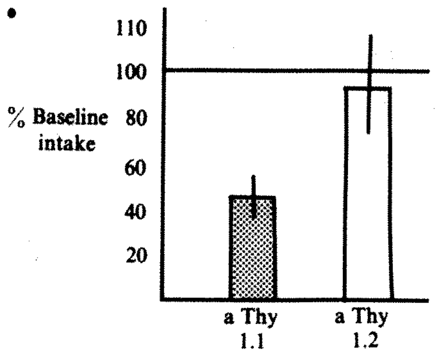

Fig. 2 Comparison of the effects of intrahypothalamic monoclonal antibodies T32B11 (aThy-1.1) and F7D5 (aThy-1.2) on carbamyl choline (CC) stimulation. Data are expressed as percentage of water intake by carbamyl choline (0.8 μg in 1 μl)-stimulated animals following treatment with aThy-1.1 or treatment with aThy-1.2 (serum diluted 1/5) 6 h before injection of drug into the perifornical hypothalamus. ($n = 12$.) Error bars show ±s.e.m.

Figure 1 shows that NA elicited excessive eating while CC elicited excessive drinking, confirming the work of other investigators on the adrenergic and cholinergic regulation of appetitive behaviour at this site[18–21]. Drinking after NA injection and eating after CC injection did not differ significantly from consumption in saline control conditions. Following treatment with aThy-1.1 antibody the drinking response to CC was significantly reduced ($P < 0.02$), whereas neither the drinking nor the eating responses in any other treatment conditions were significantly altered. Repeated baselines with CC indicated complete recovery of the drinking response by 3 days.

These animals were also tested with aThy-1.2, specific for the alloantigenic variant not found in the rat. This was done to control for the possibility that the selective reduction of CC induced drinking was a nonspecific effect, either of some mouse serum component or a hybridoma secretion other than antibody. aThy-1.2 was used at the same protein concentration as aThy-1.1, but only CC-stimulated drinking was tested since that was the only behaviour affected by aThy-1.1. Figure 2 shows the effects of aThy-1.1 and aThy-1.2 on CC-stimulated drinking. Treatment with aThy-1.1 reduced CC-stimulated drinking by $>50\%$, whereas the reduction of mean water intake observed after treatment with aThy-1.2 was not significantly different from the CC baseline. Although aThy-1.1 and aThy-1.2 were allotype-specific, the effect of the high serum concentration of the initial experiment might have been due to some other antibody or substance in the aThy-1.1 serum. The animals were tested, therefore, in groups of eight at aThy-1.1 dilutions of 100, 500, 5,000 and 20,000, alternating with repeat baseline determinations at weekly intervals. Six animals not consistently responding to CC stimulation in three baseline determinations were eliminated from this study. aThy-1.1 diluted 100- and 500-fold significantly reduced the drinking response to CC stimulation ($P < 0.01$). It is probable, however, that dilutions higher than 500 will show a significant effect in larger groups. Because of the activity of aThy-1.1 at 500 dilutions, equivalent to less than 1 pmol of immunoglobulin, we concluded that the effect was Thy-1 specific.

These experiments suggest that the Thy-1 antigen in the rat hypothalamus is distributed in such a way that its reaction with antibody results in a blockade of cholinergic function. The distribution of Thy-1 by structures and brain regions[1,9,15,26] is not inconsistent with a link between Thy-1 and cholinoception. However, the detection of Thy-1 over the entire surface of dorsal root ganglion neurones, which are thought to have only dendritic innervation[11,12], suggests that Thy-1 localisation is not exclusively associated with synapses. Others report that brain Thy-1 is predominantly in the synaptosomal fraction[13,14]. Presynaptic Thy-1 has been demonstrated on aminergic synaptosomes by complement-mediated cytolytic release of transmitters[27], the antigen might still be associated with cholinoceptic modulation of normal release mechanisms.

Our experiments indicate no association of rat brain Thy-1 with α-adrenergic function, at least none which can be blocked by an antibody to Thy-1.1. In an earlier study using the same behavioural test we found complete suppression of NA-induced eating by two different rabbit antisera against a synaptic membrane fraction (aSM). No effect on CC-induced drinking was detectable with aSM. Conversely, a rabbit antiganglioside serum (aGS) greatly reduced the drinking response to CC without affecting NA-induced eating[28]. That study represents an important functional and methodological control even though the target antigen for aSM is not known.

The similar effects of aThy-1.1 and aGS on cholinoceptive function need not imply a common target antigen. Nor is it likely that gangliosides are antigenic determinants of Thy-1 antigens. The aGS we used (preparation 2229 supplied by Dr M. M. Rapport) was raised against whole beef brain gangliosides and it is reported to react with GM_1, G_{D1b} and asialo-G_{M1}, but not with G_{D1a} or G_{T1} gangliosides[29]. It is possible that some antibody in this antiserum cross-reacts with a carbohydrate determinant present on rat brain Thy-1 antigen. To test this possibility, we isolated the IgG fraction of the aGS serum on a staphylococcal protein A-Sepharose 4B column[30]. By radioimmunoassay with ^{125}I-protein A, we find significant binding of aGS2229–IgG to purified rat brain Thy-1 antigen (supplied by Dr A. F. Williams). Consistent with the different carbohydrate composition reported for rat thymocyte Thy-1[23,24], we are unable to demonstrate binding of aGS2229 immunoglobulin to rat thymocytes by indirect immunofluorescence.

These experiments have tentatively assigned a functional correlate to the Thy-1 antigen. Determination of the mechanisms by which aThy-1.1 causes behavioural alterations remain to be investigated. As full responsiveness was recovered in 3 d or less, it is unlikely that the effects are caused by complement-mediated cytotoxic lesions. More likely is the proposal of Barclay *et al.*[23] and Williams *et al.*[24], that the protein mediates a common and special cellular function wherever the Thy-1 antigen is found; the carbohydrate, which may vary from one tissue to another, contributes a specificity to the cell's reactions with other cells and with substances in the extracellular environment. The binding of aThy-1.1 to the protein may affect the function of the molecule by steric hindrance of the carbohydrate specifying function, or by causing a conformational constraint in the protein, or by cross-linking the complex into a nonfunctional array in the cell surface.

We thank Drs A. N. Barclay, K. L. Fields, M. C. Raff and A. F. Williams for helpful comments, and Dr E. A. Clark for hybridoma antibody and Ms Judith Drayton for technical assistance. Respiratory oscillations in arterial carbon dioxide tension as a control signal in exercise

D. M. Band

Sherrington School of Physiology, St Thomas's Hospital Medical School, London, UK

G. M. Cochrane & J. Prior

Department of Medicine, Guy's Hospital, London, UK

We have monitored oscillations in arterial *p*H (of respiratory frequency) in normal man at rest and during exercise. The *p*H oscillations are known to reflect respiratory oscillations in arterial carbon dioxide tension generated at the lungs. We have found that the *p*H oscillations increase in their upslope and downslope during exercise. This means that oscillations in arterial carbon dioxide tension can be considered as a control signal.

During exercise there is a considerable increase in the ventilation of the lungs which matches the increase in the oxygen requirement of the body and the increase in carbon dioxide production. The ventilatory increase is adequate to keep the levels of oxygen and carbon dioxide reasonably constant in the lungs and also therefore in the arterial blood. How the ventilation is so precisely adjusted to meet the need for oxygen uptake [$\dot{V}O_2$] and carbon dioxide clearance [$\dot{V}CO_2$] has remained obscure in spite of our knowledge of receptors sensitive to altered levels of arterial tensions of both oxygen (the peripheral arterial chemoreceptors) and carbon dioxide (principally the central—medullary—chemoreceptors). Because the arterial levels of oxygen tension [P_aO_2] and carbon dioxide tension [P_aCO_2] do not change much in exercise, Yamamoto suggested that P_aCO_2 oscillations of respiratory frequency might be present and, theoretically at least, would convey information as to $\dot{V}CO_2$ (ref. 1). For P_aCO_2 oscillations to be a reasonable candidate as a control signal in exercise they must get bigger—or at least steeper. The peripheral arterial chemoreceptors are now known to have a high dynamic sensitivity to P_aCO_2 oscillations in the anaesthetised cat[2], although for technical reasons the P_aCO_2 oscillations are measured indirectly, as changes in acidity, with a fast response *p*H electrode. Although direct measurement with a PCO_2 electrode would be preferable none respond sufficiently fast. Even the fast response *p*H electrode

0028–0836/80/010084—02$01.00

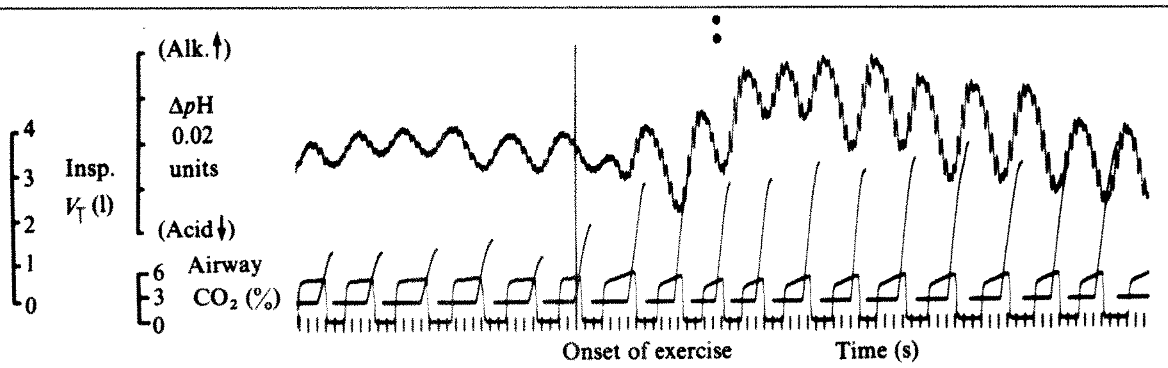

Fig. 1 Photographic record of arterial *p*H oscillations before and after the onset of exercise (40 W) in a healthy subject (C.B.W.). The records below the arterial *p*H record, monitored by means of a left brachial artery cannula, are inspiratory (Insp.) tidal volume (V_T), the airway carbon dioxide concentration, and lines showing the passage of time in seconds. VCO_2 and the average of upslope and downslope of the *p*H oscillations (d*p*H/d*t*) increase 2.7 times with exercise. $\dot{V}CO_2$ increases from 304 to 827 ml min^{-1} BTPS; d*p*H/d*t* from 4.41×10^{-3} to 11.95×10^{-3} *p*H units per second.

systems have so far been highly vulnerable to movement, with excessive electrical noise on any attempt to use them for the indirect measurement of P_aCO_2 oscillations in exercise.

Most of the electrical interference problems have been avoided by linking a fast response *p*H electrode system to a small radio transmitter, while monitoring arterial *p*H from subjects exercising on a bicycle ergometer. This has made possible transmission of the signal to a remote receiver. It has therefore been possible to monitor respiratory oscillations of the arterial *p*H in exercise. We found (Fig. 1) that the *p*H oscillations become steeper during exercise, as postulated if P_aCO_2 oscillations are to be considered as a possible control signal. The change in the form of the oscillation became apparent within 10 s of the onset of exercise.

We thank T. Cowell for the telemetry system, and the MRC for a grant to G.M.C. and C.B.W.

Spread of activation and desensitisation in rod outer segments

P. A. McNaughton, K.-W. Yau & T. D. Lamb

Physiological Laboratory, Downing Street, Cambridge, UK

Visual transduction in vertebrate photoreceptors is thought to involve a diffusible internal transmitter which links photon absorption in disk membranes to the conductance decrease in the plasma membrane of the outer segment[1–5]. The desensitisation of the photoresponse which occurs during and after illumination may also involve a diffusible substance, because a photon absorbed in one disk can desensitise the cell's response to a subsequent photon absorbed in a different disk[6]. Although both activation and desensitisation spread longitudinally from the site of photon absorption, neither spreads over the entire length of the outer segment[7,8]. We report here experiments which indicate that, with dim illumination, both effects decline to be half-maximal in less than 8 μm from the site of light absorption.

A single toad rod outer segment was drawn into a closely fitting glass pipette by a recently developed technique[9] and its membrane current was measured. Narrow transverse slits of light could then be positioned as desired along the outer segment, allowing investigation of the spread of activation and desensitisation from the site of light absorption.

In Fig. 1*b* the peak current collected by the pipette, scaled by the flash intensity, is plotted as a function of the displacement of a narrow slit of light from the distal tip, for the cases in which the outer segment was almost completely (●) or only partly (□) sucked into the recording pipette, as indicated schematically in (*a*). In this way curve 2 represents a profile of recorded current as the stimulus was moved off the recording pipette, while curve 1 is a control representing the current collected from the same parts of the outer segment when it was almost completely drawn into the pipette. The shapes of the responses were similar at all stimulus positions except when the slit was some distance off the pipette tip. In this case the intensity had to be substantially increased to give a measurable response, which then exhibited a small (less than 0.5 pA) rapid inward component preceding the normal outward current change. This inward transient might be due to the unstimulated part of the outer segment acting as a current sink. When scaled by flash intensity this negative component was very small on the scale of Fig. 1.

This figure illustrates that activation caused by illumination at one point does not spread over the entire outer segment. For example, stimulation of the point on the outer segment 40 μm from the distal tip gave a measured response which was about 40 times smaller when that part of the cell was just outside the pipette than when it was inside.

The ratio of the two profiles of recorded current, plotted in Fig. 1*c*, gives a measure of the current collected by the pipette as the slit is moved off the tip, corrected for non-uniformities in the sensitivity of the outer segment. If the pipette were a perfect step collector of current (that is if it collected all the current from the region of the cell inside the point of narrowest constriction and none from outside), then the profile in Fig. 1*c* would represent the integral of the membrane current density from the tip of the outer segment to the constriction. Hence the spatial derivative (broken curve) would represent the spread of activation from the narrow line source of illumination; its width at half-height is 15 μm (arrow). This profile is considerably broader than the spread of the stimulating light. Unfortunately we have no direct measure of the collecting efficiency of the pipette, as would be needed to correct the spread function, and we can say only that the curve probably represents an upper limit to the actual spread

. 0028-0836/80/010085—03$01.00

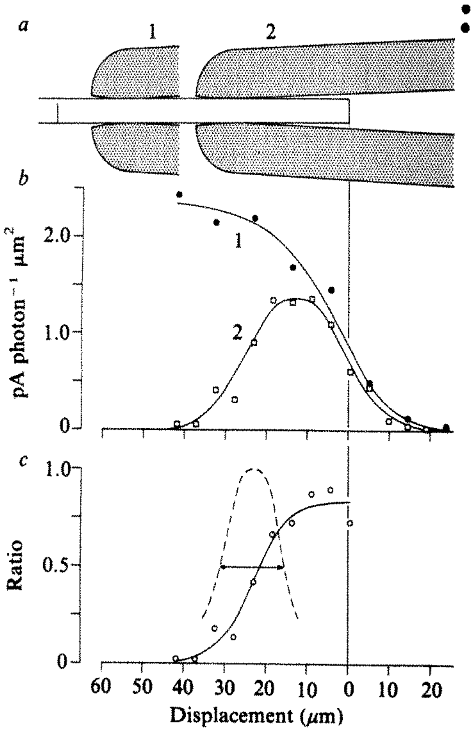

Fig. 1 Spread of activation in a rod outer segment from *Bufo marinus*. *a*, Scale diagram of the outer segment almost completely (1) and partly (2) drawn into pipette. *b*, Recorded current, divided by flash intensity, as a function of displacement of a transverse slit from the tip of the outer segment, for the two positions of the cell. Nominal slit width 6.9 μm. Saturating response of the rod to diffuse light was 18 pA. In this and subsequent figures 20 responses were averaged and flash intensity was adjusted to give approximately 2 pA response; 20-ms flash; 500-nm light plane polarised perpendicular to the long axis of the outer segment; temperature 20°–24 °C. *c*, Ratio of profiles in (*b*); ○ are the ratio of squares (□) to the curve 1 near the filled circles (●); broken curve is the normalised spatial derivative of solid curve. The right hand parts of the curves in (*b*) do not coincide, possibly because of slight movement of the tip of the cell during the experiment. For this reason the ratio has not been plotted beyond 0 μm.

of activation. We believe that this profile has not been substantially narrowed by the presence of current sinks in the unilluminated region because, as discussed above, such sink currents appear to be small. Our upper limit is in broad agreement with a previous estimate of spread in rat rods of 12 μm from the point of absorption[7].

A lower limit can be obtained from the ratio of the amplitude of the single photon event of about 1 pA (ref. 10) to the amplitude of a saturating response of about 30 pA (ref. 9). This indicates that at least 1/30 of the outer segment plasma membrane must be affected by a single isomerisation, so that for an outer segment 60 μm long activation must spread over a longitudinal region of at least 2 μm, corresponding to 1 μm either side of the point of photon absorption.

Figure 2 shows that desensitisation is also localised. Narrow slits were used for both the brief test flash and the steady adapting light, and each was presented near either the base or tip of the outer segment. The heavy traces are averaged responses to the test flashes presented during adapting illumination, while the lighter traces are controls in which the same flashes were presented in darkness. In (*a*) and (*d*) the test and adapting slits were superimposed at the base and tip respectively, while in (*b*) and (*c*) the test and adapting slits were at opposite ends of the outer segment, separated by approximately 30 μm. When they were superimposed the response to the test flash was substantially smaller and faster, but when they were at opposite ends of the outer segment the test response was unaffected by the adapting light. This experiment shows that a light which locally desensitises by three- or fourfold has negligible adapting effect at a distance of 30 μm. On all occasions when substantial desensitisation was observed it was accompanied by accelerated response kinetics, suggesting that the reduction in response amplitude was not due solely to local saturation of light-sensitive channels.

The extent of spread of desensitisation is examined in another cell in Fig. 3. Here desensitisation is expressed as the ratio of sensitivity in darkness to sensitivity in the presence of the steady adapting slit, rather analogous to a plot of threshold elevation in psychophysical experiments. Assuming that the measured profile is symmetrical (broken curve in Fig. 3), it has a width at half-height of 8 μm (arrow). The desensitisation has been plotted in this way in an attempt to obtain a linearised measure of the effect of adapting light. With diffuse illumination, toad rod sensitivity shows Weber–Fechner behaviour[6,11,12], defined by

$$\frac{S_F^D}{S_F} = 1 + \frac{I}{I_0} \qquad . \qquad (1)$$

where S_F is the sensitivity in the presence of background intensity I, S_F^D is the sensitivity in darkness and I_0 is the intensity that halves sensitivity. Note that the term $(S_F^D/S_F - 1)$ is directly proportional to adapting intensity. If we assume that light generates a diffusible substance whose concentration rises linearly with intensity, and that desensitisation at any point on the outer segment depends on the local concentration of this substance, then we can interpret the profile above the line $S_F^D/S_F = 1$ in Fig. 3 to represent the spread of desensitising substance. For comparison the measured light spread is indicated by the narrower curve in the figure; it has a width at half-height of only 2.6 μm.

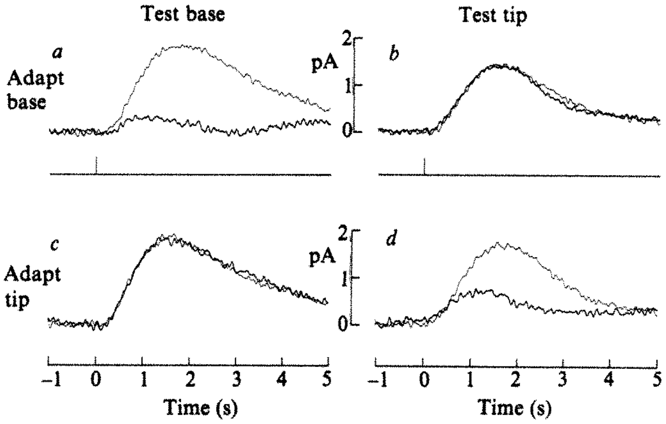

Fig. 2 Localisation of desensitisation. The test and adapting stimuli were narrow slits which could be independently positioned near either the tip or the base (as indicated) of an outer segment drawn fully into the pipette; the two slit positions were separated by about 30 μm. In each part of the figure the heavier trace is the averaged response to the test flash in the presence of the steady adapting slit, and the lighter trace is the control in darkness. Identical stimuli were used throughout; adapting slit gave steady response of about 3 pA at both positions; nominal slit widths 6.9 μm. Saturating response to diffuse light was 20 pA. Responses low-pass filtered at 10 Hz.

Some justification for the linearising procedure adopted in the previous paragraph comes from a comparison between the effects of local and uniform illumination. In Fig. 3 the adapting slit delivered about 7 photoisomerisations per s and the area under the profile of $(S_F^D/S_F - 1)$ was 54 μm. If the same number of photoisomerisations were spread uniformly over the whole outer segment length of 60 μm then the average value of $(S_F^D/S_F - 1)$ would be 54 μm/60 μm = 0.9. Thus the intensity

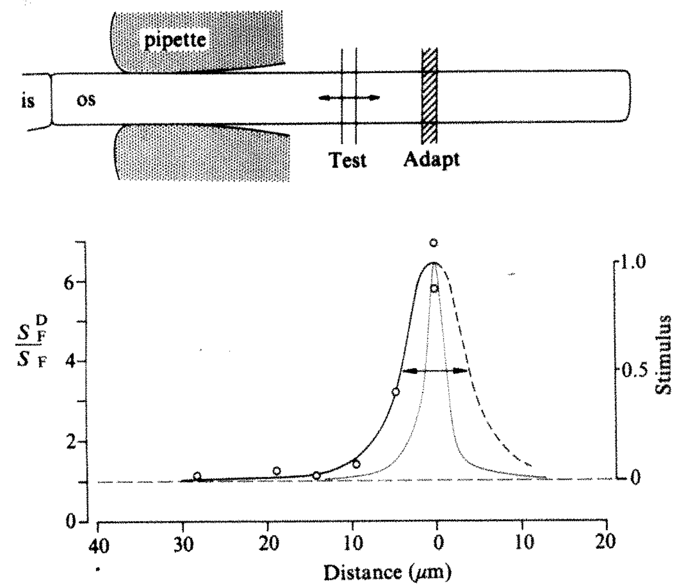

Fig. 3 Spread of desensitisation. Top: diagram of outer segment and light slits on the same scale as the lower abscissa. Bottom: desensitisation, expressed as dark sensitivity (S_F^D) divided by sensitivity (S_F) in the presence of the adapting light (left-hand ordinate, open circles; heavy curve fitted to the points by eye, and assumed to be symmetrical to obtain the broken extension), as a function of distance between the steady adapting slit and the test flash slit (abscissa). The position of the steady adapting light was fixed (0 μm on abscissa) and the test flash was moved to different positions on the outer segment. The thin line shows the normalised intensity (right-hand ordinate) of the adapting slit, determined in another experiment by moving the image of the slit across a small aperture placed in the microscope eyepiece. Both slits had a nominal width of 1.7 μm. The steady light had a nominal intensity of 4.6 photons $\mu m^{-2}\,s^{-1}$, and produced a mean response of 2.2 pA. Saturating response to diffuse light was 16.4 pA.

I_0 of diffuse light required to halve the sensitivity (that is, $S_F^D/S_F - 1 = 1$) would be $7/0.9 = 7.8$ photoisomerisations per s. This is in reasonable agreement with measured values of about 4 photoisomerisations per s[6,11,12].

Preliminary experiments indicate that the integration time[13] of desensitisation resulting from flash illumination is about 3.5 s. Applying this value and equation (1) to the cell in Fig. 3 we estimate that, during this integration time, a single photoisomerisation should on average reduce sensitivity by about 18% (that is $S_F/S_F^D \simeq 0.82$) at the site of light absorption.

We conclude that the spread of activation and desensitisation is restricted mainly to a distance of 5–10 μm along the outer segment from the site of photon absorption. The extent of spread of desensitisation lies between our upper and lower estimates for spread of activation, and it is possible that both effects spread to the same extent, as would be the case if the same diffusible substance were ultimately responsible for both processes.

Localisation of substance P immunoreactivity in amacrine cells of the retina

H. J. Karten & N. Brecha*

Department of Psychiatry and Behavioral Science,
School of Medicine—Health Sciences Center,
State University of New York at Stony Brook, New York 11794

Since its actions on smooth muscle were first described by von Euler and Gaddum[1], substance P has been isolated and characterised as an undecapeptide[2,3]. The distribution of substance P-like immunoreactivity in both the central and peripheral nervous systems[4,5] and its reported excitatory action on neurones implicate substance P as a possible neurotransmitter and/or neuromodulator[6,7]. Previous studies using bioassay[8,9] and radioimmunoassay[10,11] techniques have reported substance P in retinal extracts. Here we describe the specific immunohistochemical localisation of substance P-like immunoreactivity in a population of morphologically distinct amacrine cells of the pigeon retina. The localisation of substance P-like immunoreactivity and the recent localisation of enkephalin-like[12,13] and somatostatin-like immunoreactivity[14] in other types of amacrine cells suggest that the neuropeptides have a specific role in retinal function.

Details of the methods used for localisation are described in the legend to Fig. 1. Substance P-like immunoreactivity was observed only in the inner nuclear and inner plexiform layers of the retina with both the indirect immunofluorescence and immuno-peroxidase bridge procedures. Specific substance P-like immunoreactivity was observed in the somata of amacrine cells usually located at the border of the inner nuclear and inner plexiform layers (Figs 1*a*, 2). No immunoreactive somata were observed in the outer nuclear layer, the distal inner nuclear layer or the ganglion cell layer. Muller cells were not immunoreactive. Immunoreactive cell processes were observed only in the inner plexiform layer.

The immunoreactive amacrine cells have a single process, which descends directly into the inner plexiform layer and ramifies in a narrow band of the inner plexiform layer corresponding to lamina 3 of Cajal[15]. Substance P-like immunoreactivity was observed in both central and peripheral retinal regions. The immunoreactive amacrine cells in the tangential sections were about 7 μm in diameter and were distributed throughout the retina. Relative to other retinal regions, a greater number of immunoreactive somata were located in the inferior retina and a smaller number of immunoreactive somata were located within the red field of the superior retina.

The staining for substance P seems to be specific, as it was eliminated by incubation of the retinal sections in substance P monoclonal antiserum preabsorbed with 10 μm synthetic substance P (Fig. 1*b*). Moreover, retinal sections incubated in substance P antiserum preabsorbed with 10 μM synthetic neurotensin, Leu^5-enkephalin, Met^5-enkephalin, somatostatin or thyrotropin-releasing factor demonstrated positive immunoreactivity in the same type of amacrine cell, indicating that the substance P antiserum did not react with these other peptides in our incubation conditions. Incubation of retinal sections in either normal or preabsorbed antisera demonstrated nonspecific immunoreactivity in a few ganglion cells located in the peripheral retina.

The present study demonstrates a specific population of substance P-like immunoreactive amacrine cells and their processes in the avian retina. The consistent size of their somata,

their location in the proximal inner nuclear layer and arborisation pattern in lamina 3 of the inner plexiform layer suggest that neither bipolar cells nor displaced ganglion cells contain substance P-like immunoreactivity[15,16]. The profile of the substance P-like immunoreactive cell is similar to amacrine cell type 'J' described by Cajal[15] from Golgi material. On the basis of somatic location and arborisation patterns, the substance P-like immunoreactive cells do not seem to overlap with the indoleamine[17] or dopamine[18] containing amacrine cells.

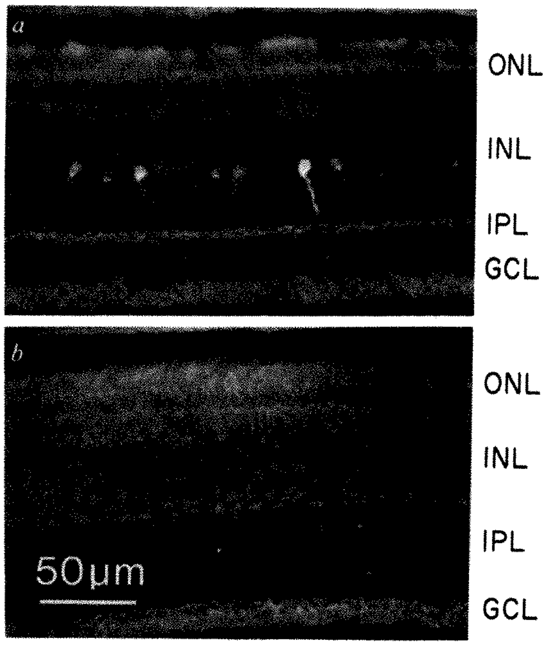

Fig. 1 *a*, Low power photomicrograph of a retinal section incubated in substance P antiserum demonstrating substance P-like immunoreactivity in an amacrine cell and in processes located in the inner plexiform layer. Several other substance P-like immunoreactive somata occur in a different plane of focus. *b*, Low power photomicrograph of a retinal section incubated in substance P antiserum which had been preabsorbed with 10 μM synthetic substance P, demonstrating lack of substance P-like immunoreactivity. ONL, outer nuclear layer; INL, inner nuclear layer; IPL, inner plexiform layer; GCL, ganglion cell layer. Retinal sections for Figs 1 and 2 were prepared as follows. Adult white Carneaux pigeons were deeply anaesthetised with intramuscular ketamine and perfused through the left ventricle with 6% dextran in 0.1 M phosphate buffer (*p*H 7.2) followed by 4% paraformaldehyde in 0.1 M phosphate buffer (*p*H 7.2). During the perfusion the eyes were injected with the fixative. They were postfixed for 4–6 h at 4 °C and stored overnight in 30% sucrose phosphate buffer at 4 °C. Sections were cut perpendicular to the vertical axis of the eye (horizontal plane) at 12 μm with a cryostat or tangential to the retinal surface at 30 μm with a freezing microtome. They were processed for immunohistochemical staining using either the indirect immunofluorescence or the immunoperoxidase bridge techniques previously described[13]. Sections were incubated in substance P antiserum or substance P antiserum which had previously been absorbed with either 10 μM synthetic substance P, neurotensin, Leu^5-enkephalin, Met^5-enkephalin, somatostatin or thyrotropin-releasing factor at a dilution of 1:1,000 for 12–48 h at 4 °C. These experiments were replicated with at least 12 retinae except for the preabsorption series of neurotensin, Leu^5-enkephalin, Met^5-enkephalin, somatostatin and thyrotropin-releasing factor, which were replicated with two pigeon retinae.

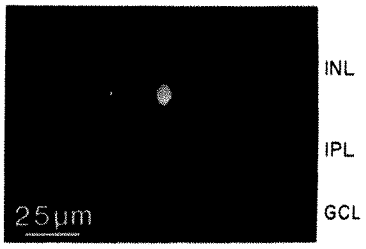

Fig. 2 High power photomicrograph demonstrating a substance P-like immunoreactive amacrine cell.

The localisation and distribution of substance P-like immunoreactive amacrine cells differ from those of enkephalin-like immunoreactive amacrine cells in the avian retina[13]. Enkephalin-like immunoreactivity has been observed in many small amacrine cells, giving rise to a diffuse plexus of processes which ramify in laminae 1 and 3–5 of the inner plexiform layer. In contrast, the substance P-like immunoreactive amacrine cells, although also small, ramify in lamina 3 of the inner plexiform layer. The enkephalin-like immunoreactive amacrine cells are distributed throughout the entire retina, are most numerous in the red field of the superior retina and may be related to the total number of cells in the inner nuclear layer[19]. The distribution of substance P-like immunoreactive amacrine cells, however, does not seem simply to be related to the total number of cells in the inner nuclear layer in as much as the greatest numbers of substance P-like immunoreactive cells are in inferior retinal regions and not the red field. The differential distribution of substance P-like immunoreactivity suggests a histochemical as well as a morphological basis for classification of retinal amacrine cells. Amacrine cells have been classified on the basis of their histofluorescent characteristics and their differential uptake systems for γ-aminoglutamic acid, glycine, choline or dopamine[20–23]. However, the total number of amacrine cells and the distribution of subclasses of amacrine cells in the retina are unknown. Therefore, it is not yet possible to compare the number of substance P-like and enkephalin-like immunoreactive amacrine cells with other histochemically distinct subclasses of amacrine cells.

Recently, several neuropeptides have been found in the retina of different vertebrate species using radioimmunoassay techniques[24–28]. Substance P-like, enkephalin-like, neurotensin-like and somatostatin-like immunoreactivity have been localised in distinct classes of amacrine cells of different vertebrate retinas using the immunohistochemical technique (refs 12–14 and unpublished observations).

In conclusion, specific substance P-like immunoreactivity occurs in a distinct class of retinal amacrine cells. The specific functional role of substance P or any other neuropeptide in the retina is unknown although their localisation in selected populations of retinal cell types suggest they have unique roles in retinal processing.

Removal of the synaptic target permits terminal sprouting of a mature intact axon

Kenneth J. Muller & Sheryl A. Scott*

Department of Embryology, Carnegie Institution of Washington,
115 West University Parkway, Baltimore, Maryland 21210

When the central nervous system (CNS) develops, neurones send out axons to make contact with appropriate synaptic target cells and then stop growing. If its usual target is missing, an axon may continue to grow until it synapses with a suitable but inappropriate target[1]. This suggests that contact with a synaptic target is important in stopping axonal growth during development. Many classes of neurone in the adult CNS retain a capacity to grow towards denervated targets[2-5], but it is not known whether the synaptic contacts established during development continue to regulate the growth of individual mature, intact axons. This has been a difficult problem to investigate; in vertebrates most studies necessarily involve large populations of neurones, and the most direct approach, removal of a synaptic target, usually damages many neurones, including the axons that are to be studied. We report here a demonstration of target cell influences on the growth of a single mature, intact axon in the CNS of the leech by selectively destroying the axon's synaptic target without injuring the axon itself. Target removal, which itself does not trigger sprouting of intact axons, permits the intact axon to grow at its tip in response to injury of other axonal branches of the same cell.

The system of S-interneurones in the leech has been particularly useful for studies of axonal growth and synapse regeneration[6-8]. In each of the 21 segmental ganglia there is one S-cell; it extends an axon both anteriorly and posteriorly about halfway along the connectives (the axon bundles that link adjacent ganglia) to make an electrical synapse exclusively with the tip of the next S-cell axon[8]. For brevity, we shall use the 'target' of the S-cell axon to denote the neurone with which that axon is synaptically linked. In this sense, each of the two synaptically coupled S-cell axons is the target of the other.

To test whether contact with a synaptic target has any influence on mature intact axons, we selectively killed single S-cells in the nervous system of an otherwise intact leech by injecting the soma of the target cell with a protease (Type VIII, Sigma)[9,10]. This approach was taken because it is not possible to eliminate the target by removing its soma, as the S-cell axon can survive for weeks severed from its cell body. Protease-injected S-cells were rapidly and completely destroyed, with no direct electrophysiologically or morphologically measurable effects on other cells[9,10]. The long-term effects on the uninjured S-cells adjacent to the killed cell were followed by dissecting chains of ganglia from 4 days to 6 months after the operation, impaling the S-cells with microelectrodes, and injecting them with horseradish peroxidase (HRP), a marker that does not cross the S-cell synapse but fills the injected cell[8], or with Lucifer Yellow, a fluorescent dye that does cross between electrically coupled cells[10,11], or with both. We studied 15 neurones in 14 preparations using electrophysiological methods, and stained and examined them with light and electron microscopy.

The S-cell axons that had been coupled to the killed cells were apparently unaffected by the loss of this synaptic contact. The neurones maintained full-calibre axons that extended to the original site of synapse with the killed cell, about halfway along the connectives, and they showed no signs of growth or retraction. The intact axons did not develop recognisable growth cones filled with characteristic smooth membranous reticulum[8,12]. Furthermore, the free axons apparently did not form synapses with other axons in the connectives. Lucifer Yellow dye provides one test for electrical synapses that resemble those made between normal S-cells. When injected into either a normal or a regenerated S-cell, the dye readily diffuses down the axons and selectively fills the adjacent S-cells, crossing into them at the electrical synapse (S.A.S. and K.J.M., in preparation). In contrast, Lucifer Yellow injected into S-cells that were adjacent to a killed cell stopped abruptly at the tip of the free, intact axon midway along the connectives, and filled no other axons (S.A.S. and K.J.M., in preparation). Moreover, no structures resembling electrical[8] or chemical[13] synapses were seen near the tips of such intact axons when viewed in the electron microscope. Thus, an S-cell axon does not seem to be affected when its unique synaptic target is selectively destroyed.

One obvious difference between neurones in developing nervous systems and those in adults that could account for the failure of the adult neurone to respond to the loss of a target is that in the adult the neurone is no longer growing when its target is destroyed. To prompt the adult S-neurone to mobilise its cellular machinery for growth, we injured the cell by severing one of its two principal axons. The target of the neurone's other, intact axon was then removed by injecting that target cell with protease (Fig. 1*a*). A total of 22 intact axons of injured neurones in 12 preparations were examined from 9 days to 6 months after surgery. Identical results were obtained whether a cell's anterior target or its posterior target S-cell was killed.

The severed axon of these cells regenerated normally[8] to form an electrical synapse selectively with the tip of the adjacent S-cell axon in about 1 month, but the response of the intact axon was surprising. Ordinarily, when one S-cell axon is severed, the cell's other, intact axon is not measurably affected by the lesion;

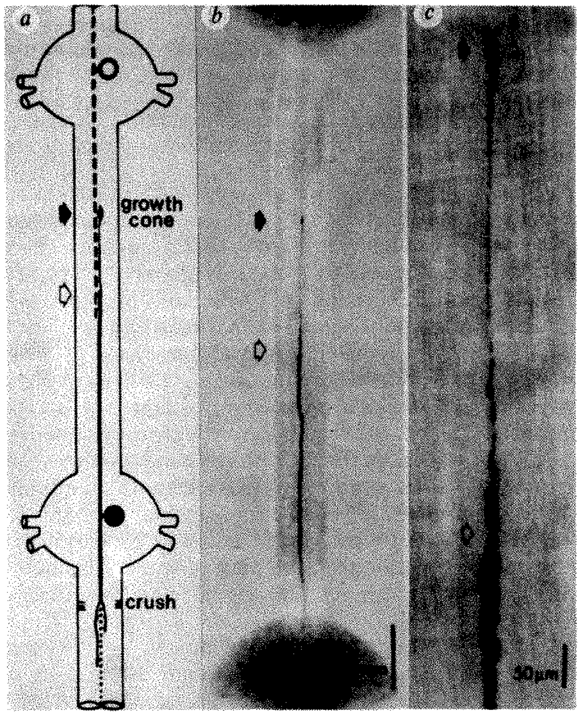

Fig. 1 An intact axon can be made to sprout when its synaptic target is selectively removed. The neurone in the ganglion at top (anterior) was injected with protease, which destroyed the entire cell (dashed line and open circle in *a*). A distant axon of the adjacent S-cell was then severed by crushing the connective (crush). The injured axon regenerated in a normal fashion across the crush and along its severed distal stump (dotted line, *a*); the intact axon of that cell, which had been in synaptic contact with the killed cell near the connective midpoint (open arrow), sprouted a fine process tipped with a growth cone (solid arrow). In *b* the sprouting neurone was marked by intracellular injection of horseradish peroxidase 25 days after its posterior axon (not visible) had been severed. *c*, The sprouted axon is seen at higher magnification, showing the growth cone (solid arrow) extending from the original axon tip (open arrow). This tissue was not cleared so that it could be subsequently examined in the electron microscope.

---

*Present address: Department of Neurobiology and Behavior, State University of New York at Stony Brook, Stony Brook, New York 11794.

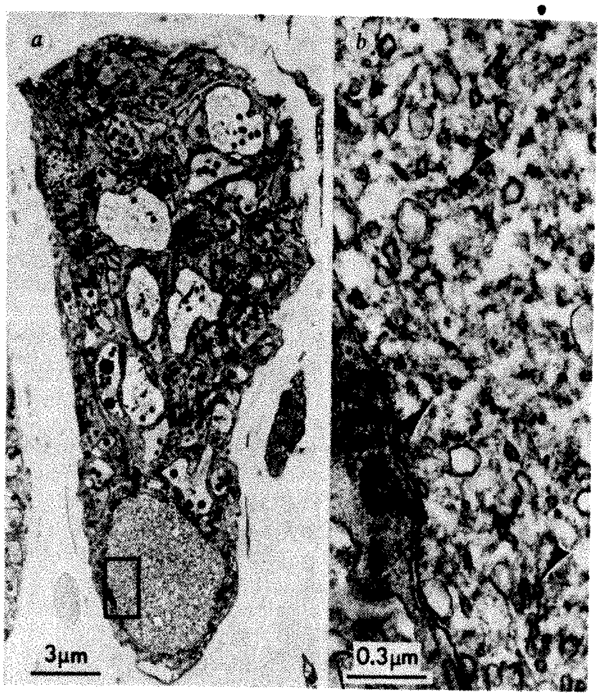

Fig. 2 The axon that sprouts in response to the loss of its target grows along the path of the destroyed cell. The sprouted neurone was marked with intracellular injection of horseradish peroxidase 38 days after the adjacent S-cell had been killed. The electron micrograph in *a* shows a cross-section of the connective cut through the growth cone of the sprouted axon, which is located at the position in the middle connective (Faivre's nerve) that is normally occupied by the killed cell. The growth cone contains much smooth membranous reticulum (arrowheads in *b*, an enlargement of boxed region of *a*) characteristic of the tips of growng axons.

it remains in synaptic contact with its target and does not grow[8]. In striking contrast, the intact axon of the injured neurone sprouted at its tip when its target was destroyed with protease. Most intact axons of injured S-cells eventually grew about half the distance from the original axon tip, which was clearly recognisable (Fig. 1), to the next ganglion; one axon grew as far as the adjacent ganglion. Terminal sprouting was most obvious in cells examined 3–6 weeks after surgery. In these cells a single fine process, enlarged at the tip to a growth cone, extended from the end of the intact axon (Fig. 1). Electron microscopy showed that the growth cones were filled with a smooth membranous reticulum and that they followed a route indistinguishable from that formerly occupied by the killed S-cell (Fig. 2). Although this route might simply have been the path of least resistance, the possibility remains that it was actively selected, as is evidently done by regenerating axons[8].

The sprouted axons stopped growing during the second month after surgery, apparently without establishing any synaptic contacts. Electron micrographs of the tips of the sprouted axons showed that the growth cone together with its content of smooth membranous reticulum disappeared, and that no structures resembling chemical or electrical synapses had formed. Furthermore, Lucifer Yellow injected into sprouted S-cells filled the intact axon to its tip without passing into other axons; this paralleled HRP labelling of the same cells (S.A.S. and K.J.M., in preparation). Under the present circumstances, the sprouted S-cells may have failed to establish synapses in the connectives simply because unoccupied targets were not available. Had the connective itself been injured, the sprouted axons may then have formed synapses with alternative targets[5,14].

In most preparations examined more than 3 months after surgery, the tip of the S-cell axon was not as fine and long as in preparations examined at earlier times, suggesting that sprouts may begin to retract if they fail to find a suitable target. However, we have seen no evidence of a complete retraction of the sprouts; even at the longest times it was clear that a sprout extended from the original tip of the axon, which remained distinct.

Thus, removal of the synaptic target of a mature, intact axon in the CNS of the leech permits the axon to sprout if the neurone itself has been triggered to grow by direct injury to another of its branches. Neither simple elimination of the synaptic target nor injury to another axon of the cell is sufficient to induce sprouting, although if new targets could be made available the neurone might sprout[1,3]. We do not know what aspect of cellular injury prompts terminal sprouting of an intact, denervated axon, nor do we know the signal that stops axonal growth, as the axon does not form synapses. It might be that growth stops when the cell reaches some maximal arborisation, or that all growth ceases soon after the severed axon stops regenerating. The findings reported here suggest the possibility that axonal injury triggers general growth processes in the damaged neurone, like those in developing neurones, expressed only by axonal branches that have lost contact with their targets. Although it is not known how the target exerts its effects on the axon, whether by impulse activity across the synapse, transfer of molecules between the coupled cells, direct physical contact, or some other means, it is clear that in the adult nervous system synaptic contacts can inhibit the growth of intact axons.

We thank Ms Barbara Thomas for technical assistance and Drs Ellen Elliott, Doug Fambrough and Eric Wakshull for helpful suggestions. Lucifer Yellow was a gift of Walter Stewart. This work was supported in part by a NIH Fellowship to S.A.S. and NIH grant NS 15014.

Pirenzepine distinguishes between different subclasses of muscarinic receptors

R. Hammer*, C. P. Berrie, N. J. M. Birdsall, A. S. V. Burgen & E. C. Hulme

Division of Molecular Pharmacology, National Institute for Medical Research, Mill Hill, London NW7, UK

Some antagonists exhibit tissue selectivity in their pharmacological antagonism of muscarinic responses[1]. However, the affinity constants for equilibrium binding of classical antagonists to muscarinic receptors in subcellular preparations have shown only small variations in different peripheral tissues and regions of the brain[2–6]. The binding curves do not deviate significantly from the simple Langmuir isotherm, indicating apparent homogeneity of the receptor population in any given region [5–8]. In contrast, heterogeneity has been detected by agonist binding studies[8,9] but this may arise from different environmental or coupling restraints on the agonist-induced conformational change[10,11] and cannot be taken as evidence for different receptor subtypes. We report here binding studies using a new anti-muscarinic drug, pirenzepine, in which we found heterogeneity of binding that correlates well with the pharmacological activity.

Pirenzepine (LS 519 Cl2), (Fig. 1) inhibits gastric secretion in animals[12] and man[13–15], and there is strong evidence that this effect is governed by an antimuscarinic mechanism[16,17]. It also antagonises the cholinergically stimulated contraction of the smooth muscle of the ileum[18] and urinary bladder[19], blocks salivation, and causes tachycardia[19]. However, in contrast to the action of classical antimuscarinic drugs, there is a wide disparity between the doses of pirenzepine needed to evoke these different effects; whilst effects on gastric secretion are seen at very low doses, higher doses are needed to inhibit salivation, and only with very high doses are effects seen on the smooth muscle of the stomach wall and on the heart[19,20]. Central effects are not significant since the drug is hydrophilic[21] and therefore does not cross the blood barrier to any appreciable extent[22]. In the present study the binding of pirenzepine to muscarinic receptors in homogenates of several peripheral tissues and in different regions of the rat brain has been compared to that of a classical muscarinic antagonist, *N*-methylscopolamine (NMS).

The binding of NMS was determined directly using the radiolabelled ligand ^{3}H-NMS (refs 7, 9) and representative binding curves in the sublingual gland and atria are shown in Fig. 2. There is only a small difference in the two estimates of the ^{3}H-NMS dissociation constant in the two tissues and in all the areas examined the ^{3}H-NMS binding curves are adequately described by a simple Langmuir isotherm having Hill coefficients (H) close to, or not significantly different from 1.0 (Table 1).

Table 1 Pirenzepine and NMS binding in peripheral organs and in brain

Region	Pirenzepine $IC_{50\,cor}$(M)	H	NMS K_d(M)	H
Brain				
Hippocampus	3.4×10^{-8}	0.80*	2.7×10^{-10}	1.05
Cerebral cortex	5.1×10^{-8}	0.73*	3.6×10^{-10}	1.00
Medulla-pons	4.1×10^{-7}	0.97	4.5×10^{-10}	1.04
Glands				
Sublingual	1.1×10^{-7}	0.72*	3.0×10^{-10}	0.91
Submandibular	1.3×10^{-7}	0.78*	2.5×10^{-10}	1.01
Lacrimal	2.0×10^{-7}	0.97	3.2×10^{-10}	1.04
Parotid	2.9×10^{-7}	0.97	2.6×10^{-10}	0.90
Heart and smooth muscle				
Atria	8.3×10^{-7}	0.96	5.9×10^{-10}	0.96
Ileum wall	7.9×10^{-7}	0.96	6.7×10^{-10}	0.96
Stomach wall	1.1×10^{-6}	0.98	5.3×10^{-10}	1.08

All manipulations and assays were performed in 100 mM NaCl, 10 mM $MgCl_2$ 20 mM HEPES (*p*H 7.5). The salivary glands, lacrimal gland and atria were homogenised initially in buffer (Sorvall Omnimix, setting 4, 60 s, 0 °C). The ileum and stomach wall were dissected free of mucosa and homogenised (Ultra-Turrax, setting 6, 2 × 30 s, 0 °C). All initial homogenates of peripheral organs were further homogenised (Potter–Elvehjem, 20 strokes, 520 r.p.m., 0 °C) and filtered through cheesecloth. It was found that the presence of the proteolytic inhibitor, phenylmethylsulphonylfluoride (1 mM) had little effect on the receptor binding properties. The brain regions were only subjected to the Potter homogenisation. For the binding assays the homogenates in appropriate dilutions (~1 mg protein ml^{-1}) were preincubated for 10 min at 30 °C before addition to microcentrifuge tubes containing labelled ligands with or without unlabelled ligands. Incubation was carried out for 20 min (at which time, binding was at equilibrium) at 30 °C and was terminated by centrifugation as previously described[7]. Assays were carried out in quadruplicate and the non-specific binding defined as the radioactivity bound or entrapped in the pellet when the incubation medium contained 10^{-6} M 3-quinuclidinyl-benzilate. Binding curves for NMS were measured directly with the radio-labelled ligand. Binding curves for pirenzepine were derived indirectly from competition studies against 3×10^{-10} M ^{3}H-NMS (peripheral organs), or 10^{-9} M ^{3}H-propylbenzilylcholine (brain regions) as described previously[7]. K_d for NMS were estimated from ^{3}H-NMS saturation curves according to a one-site model using non-linear least squares regression analysis[7]. The IC_{50} values for pirenzepine binding were corrected for the radioligand occupancy shift according to $IC_{50\,cor} = IC_{50}/(1+[C]/K_d)$, where K_d and [C] represent the dissociation constant and the concentration of the radioligand respectively. H values were calculated by linear regression analysis and analysed for statistically significant deviation from unity. The data are, in general, the mean of at least two independent measurements which differed in IC_{50} value by less than 20%.

* Significantly different from 1 ($P < 0.05$).

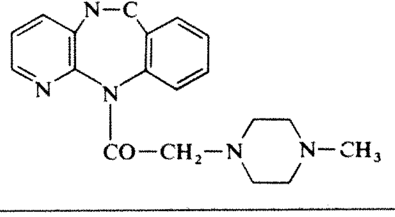
The binding of pirenzepine was determined by the inhibition of receptor-specific binding of ^{3}H-propylbenzilylcholine or ^{3}H-NMS (refs 7, 9). Occupancy concentration curves for pirenzepine binding in preparations from the cerebral cortex, sublingual gland, parotid gland and atria are shown in Fig. 2. Experimental details are given in the legend to Table 1. It is clear that there are large differences in the concentrations of pirenzepine giving 50% occupancy of the receptors in the various regions. The pirenzepine binding curves in the parotid and atria have H-values close to 1.0, whereas the binding curves for pirenzepine in the cortex and sublingual gland deviate significantly from unity (Fig. 2, Table 1) suggesting the presence of sites of more than one affinity[8,9]. Nonlinear least-squares regression analysis shows that the presence of two populations of sites having dissociation constants (K_d) of 2.5×10^{-8} M and $0.7–1.0\times10^{-6}$ M are needed to adequately account for these flat curves. Preliminary direct binding experiments also show that low concentrations of ^{3}H-pirenzepine bind specifically to a high affinity population of sites in the cortex, with K_d of 2.5×10^{-8} M, thereby confirming the indirect measurements (R.H. *et al.*, unpublished results). The pharmacological specificity and the binding properties of the high affinity ^{3}H-pirenzepine sites suggest that they are a sub-class of those labelled by ^{3}H-NMS.

Table 1 summarises a series of pirenzepine binding measurements. The lowest IC_{50} values for pirenzepine were found in the hippocampus and cerebral cortex; both areas exhibited heterogeneous binding curves. Intermediate values were found in the medulla-pons, the salivary glands and the lacrimal gland. The parotid and lacrimal glands appear to contain relatively uniform populations of pirenzepine sites, with K_d of $2–3\times10^{-7}$ M, whilst the sublingual and submandibular glands gave H values significantly less than 1.0, and appear to contain a small proportion of high affinity sites. Heart and smooth muscle were found to contain a homogeneous, low affinity population of pirenzepine binding sites ($K_d \approx 1\times10^{-6}$ M). All the pirenzepine binding data are compatible with the presence of three sites with $K_d \sim 2\times10^{-8}$ M, 2×10^{-7} M and 1×10^{-6} M respectively; an overall variation of 50-fold. In contrast, the affinity for ^{3}H-NMS varied by less than a factor of 3 and further confirms the lack of selectivity for binding of classical antagonists to muscarinic receptors from different tissues; again the lowest values were found in heart and smooth muscle with somewhat higher values in the glands and brain, perhaps demonstrating some analogy with the distribution of pirenzepine affinity constants.

The *in vitro* binding profile of pirenzepine in the peripheral organs strikingly parallels the selectivity of the pharmacological profile of the drug, both in animal tests[19,20] and in clinical trials[14,15,23–25]; even very high doses do not cause tachycardia and only occasionally are mild and transient 'dry mouth' effects reported. We have not yet been able to determine the pirenzepine binding properties of the muscarinic receptors in the parietal cells of the gastric mucosa because of proteolysis and the very low concentration of binding sites.

Whilst muscarinic agonists also exhibit heterogeneity of binding, it does not appear that pirenzepine has agonist or partial agonist activity in pharmacological studies, and in addition, in the brain, the affinity profile of pirenzepine is actually opposite to that of the agonists, which show predominantly high

Fig. 1 Formula of pirenzepine.



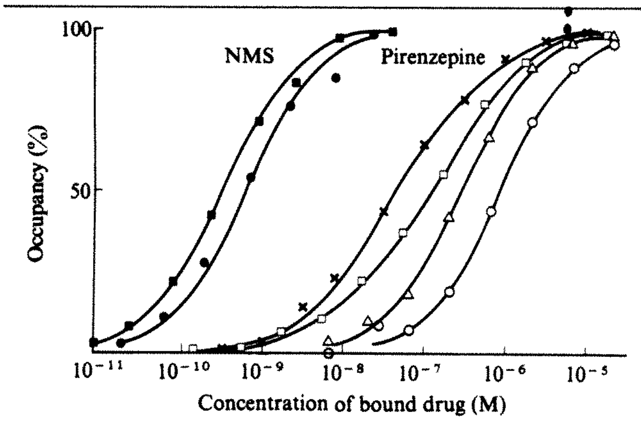


Fig. 2 Occupancy concentration curves for the binding to muscarinic receptors in different tissues of NMS (■ sublingual gland, ● atria) and pirenzepine (× cerebral cortex, □ sublingual gland, △ parotid gland, ○ atria) at 30°C. Experimental details as in the legend to Table 1.

affinity binding in the medulla-pons, and low affinity binding in the hippocampus[5]. Moreover, preliminary experiments show that the binding of pirenzepine is not affected by guanosine triphosphate in tissues, such as heart, where muscarinic agonist binding is modulated by guanine nucleotides[26]. Such behaviour is characteristic of an antagonist.

Previous evidence has favoured the hypothesis that the receptor subtypes detected by agonists do not differ in their intrinsic structure but rather in the molecules associated with them; this could equally be the explanation for the subtypes detected by pirenzepine, but we cannot yet exclude the possibility that pirenzepine senses small intrinsic differences in receptor structure.

It is evident that pirenzepine is able to discriminate differences in the subclasses of muscarinic binding sites which are not detected by classical antagonists and which make its selective antimuscarinic action possible. While the pattern of selectivity exhibited by pirenzepine favours blockade of the gastric secretogogue action of muscarinic agonists as compared with the effects on the heart, it is possible that drugs will be found with the converse selectivity.

(−)Baclofen decreases neurotransmitter release in the mammalian CNS by an action at a novel GABA receptor

N. G. Bowery, D. R. Hill & A. L. Hudson
Department of Pharmacology, St Thomas's Hospital Medical School, London SE1, UK
A. Doble*, D. N. Middlemiss, J. Shaw & M. Turnbull
Departments of Biochemistry & Biology, ICI Pharmaceuticals Ltd, Mereside, Alderley Park, Macclesfield, Cheshire, UK

The existence of a receptor for γ-aminobutyric acid (GABA) on neurones of the mammalian central nervous system (CNS) is now firmly established[1–3]. It is generally accepted that bicuculline (and its methohalide salts) is an antagonist of the actions of GABA[4,5], although resistance to bicuculline has been described[6,7]. The view that bicuculline prevents GABA from interacting with a membrane recognition site is supported by results obtained in radiolabelled ligand binding studies[8,9]. Bicuculline-sensitive GABA receptors are not confined to neurones in the CNS but are also present on neurones and axons of the peripheral nervous system[10,11]. Their existence on neurones in sympathetic ganglia made us consider the possibility that they are also present on the terminals of such neurones. This has recently been tested[12,13] by assuming that if GABA depolarises the terminals in a manner similar to the cell bodies, evoked transmitter output might be decreased (see ref. 14). GABA (ED_{50}, 4μM) clearly decreased the evoked release of accumulated ^{3}H-noradrenaline from rat atria *in vitro* and ^{3}H-acetylcholine from preganglionic terminals in the rat superior cervical ganglion *in vitro* without affecting the basal release of tritium. In neither system was the effect of GABA antagonised by bicuculline methobromide, even though the ganglion terminal depolarisation was[13]. This suggested that the two phenomena, depolarisation and inhibition of transmitter release, were separate. The decrease in transmitter release not surprisingly leads to a decrease in the postsynaptic response[15]. Again, the decrease in response was not prevented by bicuculline or other GABA antagonists. We believe that these results indicate the presence of a novel GABA receptor on nerve terminals, a theory supported by results obtained with a variety of GABA analogues. For example, 3-aminopropane sulphonic acid (3-APS) which is at least as active as GABA at bicuculline sensitive sites[10,16,17] is inactive at the terminal receptor. By contrast, the analogue baclofen (β-chlorophenyl GABA) is inactive at bicuculline-sensitive sites[18,19] but is as active as GABA in reducing evoked transmitter output[15]. This effect of baclofen is stereospecific, the (−) isomer being >100-fold more active than the (+) isomer[15]. We now report the presence of the novel GABA receptor within the mammalian CNS.

The technique used in this study was first to allow slices of CNS tissue to accumulate radiolabelled transmitter and then to examine the effect of GABA and its analogues on the basal and K^+-evoked release into fresh superfusion fluid. Three areas of the rat CNS were chosen, the cerebellum, striatum and frontal cortex. Cerebellar slices were incubated in ^{3}H-noradrenaline (13 Ci mmol^{-1}, Amersham), striatal slices in ^{3}H-dopamine (24.8 Ci mmol^{-1}, NEN) and cortical slices in ^{3}H-serotonin (29.2 Ci mmol^{-1}, NEN). The procedures adopted in each case are given in Figs 1 and 2 legends.

The rate coefficient for basal tritium release from the slices was approximately 0.4% min^{-1}. Superfusion of these slices for 2 min with Krebs' solution containing added KCl (final concentration 25 mM) increased the tritium overflow by 100–400% of the basal release. The increase was transient such that the release rate returned to the basal level by the next 4-min collection period. In every experiment the response to K^+ addition declined with repeated applications (Fig. 1*b*). K^+ additions were therefore limited to three in any one experiment. Control experiments indicated that the increase in tritium overflow in each case was Ca^{2+}-dependent. Removal of Ca^{2+}

from the superfusion fluid with the addition of EDTA (1 mM) or Mg^{2+} (2.0 mM) prevented K$^+$-induced release.

The effect of GABA and baclofen on K$^+$-evoked release of tritiated noradrenaline from cerebellar slices is shown in Fig. 1. Each histogram bar corresponds to the amount of tritium released by 25 mM KCl plotted as a percentage of the initial response. Each panel shows the mean data from five experiments. Slices from the same animal were used in one of the five experiments in each panel. Figure 1*b* shows the responses to successive additions of KCl. In Fig. 1*a* and *c*, (±)baclofen (100 μM) and GABA (100 μM), respectively, were added 1 min before the second period of superfusion with KCl. In both cases there was ~20% reduction in the expected increase in tritium overflow. When these experiments were repeated with bicuculline methobromide (100 μM) present in the superfusion medium, neither the release evoked by K$^+$ nor the reduction in evoked release produced by GABA and baclofen were affected.

3-APS (100 μM) failed to mimic the action of GABA (three experiments). Pretreatment with this GABA analogue did not reduce the K$^+$-evoked release whereas GABA (100 μM) in the same series of experiments caused the expected reduction. The effect of baclofen was stereospecific; (+)baclofen (100 μM) failed to reduce ^{3}H-noradrenaline release whereas the effect of the (−)isomer was comparable with that of the racemic form.

Similar results were obtained on the evoked release of ^{3}H-dopamine from striatal slices and ^{3}H-serotonin from cortical slices (Fig. 2). The output of both of these transmitter substances was depressed by baclofen and GABA although the response to GABA was variable. In the presence of bicuculline, however, only depressant effects were seen. 3-APS was again without depressant activity on transmitter overflow in both systems.

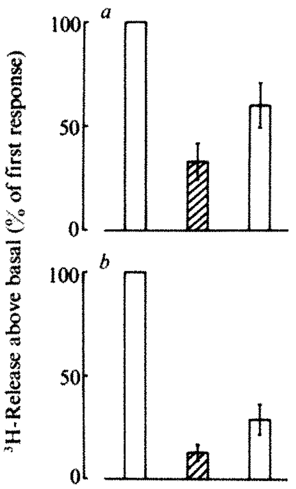

Fig. 2 Depression of K$^+$-evoked release of ^{3}H-dopamine (*a*) and ^{3}H-serotonin (*b*) by (±)baclofen. Ribbons (0.25 mm × 0.25 mm) of striatum (*a*) or frontal cortex (*b*) were obtained from 200-g male rats. The tissue was incubated for 15 min at 37 °C in 5 ml Krebs' solution containing pargyline (1 μM), ascorbic acid (0.2 mM) and either ^{3}H-dopamine (0.1 μM) or ^{3}H-serotonin (0.1 μM). The tissue was then rinsed briefly and aliquots containing approximately 5 mg tissue were transferred to 200-μl superfusion chambers. Superfusion at 0.5 ml min^{-1} was then begun but the collection of 4-min samples was delayed for a further 30 min. The tritium content of each sample was determined by liquid scintillation spectrometry. In each experiment potassium chloride (final concentration 25 mM) was added to the superfusion fluid on three occasions (for 2-min periods at 12-min intervals). The increase in tritium release provoked by each K$^+$ addition and represented by histogram bars has been plotted as a percentage of the initial response. The data in *a* and *b* are mean values ± s.e.m. derived from 16 experiments in each case. (±)Baclofen (100 μM) was present 1 min before and during the second period of K$^+$ addition.

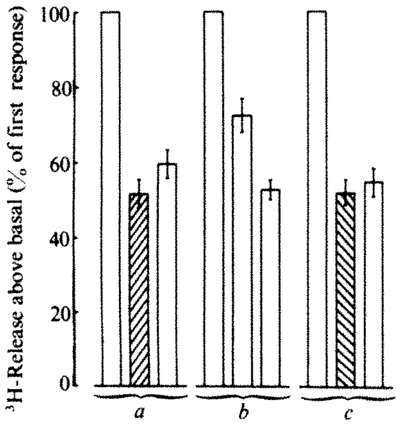

Fig. 1 Effect of GABA and (±)baclofen on the K$^+$-evoked release of ^{3}H-noradrenaline from rat cerebellar cortex slices. Three or four slices of cortex (0.25 mm thick) obtained from decapitated male rats were incubated for 20 min at 32 °C in 1 ml Krebs' solution containing 0.8 μM ^{3}H-noradrenaline, 0.5 mM iproniazid and 0.1 mM ascorbic acid. The slices were then incubated for a further 20 min in radioactive-free solution at 32 °C before transferring to a superfusion chamber. Oxygenated superfusion fluid was delivered at 0.5 ml min^{-1} and 4-min samples collected consecutively. The tritium content of each sample was determined by liquid scintillation spectrometry. Potassium chloride was added (final concentration = 25 mM) to the superfusing fluid for 2-min periods at intervals of 16 min. Each batch of three or four slices was subjected to only three additions of K$^+$. The histogram bars represent the increase above basal of the release of tritium in response to K$^+$ addition. Each has been plotted as a percentage of the initial response. The data are derived from five animals from each of which three batches of slices have been treated separately. Slices from the same animal were used for a control experiment (*b*, each bar corresponding just to added K$^+$), an experiment where (±)baclofen (100 μM) was added 1 min before and during the second period of K$^+$ addition (*a*) and an experiment where GABA (100 μM) was similarly added (*c*). Vertical lines on each bar represent s.e.m.

The possibility that GABA affects neurotransmitter release in the mammalian CNS has been previously considered by many authors. However, conflicting results have been obtained varying from no effect to facilitation of basal or K$^+$-induced release[20–30]. These variations may stem from the differences in tissue dimensions used in individual studies or from differences in the duration of superfusion with high K$^+$ and GABA. A variable which we have considered is the effect of different K$^+$ concentrations. This we have examined on the cerebellar release of ^{3}H-noradrenaline. On increasing the K$^+$ concentration to 35 mM, the reduction in evoked release produced by GABA became more apparent than that at 25 mM. However, at 15 mM K$^+$, GABA (100 μM) potentiated the evoked release (release in the presence of GABA = 113 ± 4.9% of initial response compared with 80 ± 11.0% in control experiments; means ± s.e.m., $n = 6$). Potentiation was never obtained with baclofen. Even in the presence of 15 mM K$^+$ baclofen reduced the evoked release. If the tissue was superfused with bicuculline methobromide (100 μM), the potentiation produced by GABA was reversed such that a reduction in evoked release was again observed.

Baclofen, like GABA, is a powerful neuronal depressant in the mammalian CNS and it has been suggested that this effect of baclofen stems from a suppression of transmitter release as well as from a direct postsynaptic action[18]. However, despite its close structural resemblance to GABA, baclofen is generally not considered to be a GABA receptor agonist because of its insensitivity to GABA antagonists[19,31] (but see ref. 18) and inability to displace ^{3}H-GABA from receptor binding sites[32,33] (but see ref. 34). Our findings suggest that baclofen may mimic the action of GABA at a novel site on nerve terminals. Despite failing to obtain an antagonist for this receptor, our observations[15] of cross-desensitisation, lack of additivity with supramaximal doses and parallelism of log dose–response curves in peripheral models indicate that baclofen and GABA do act at the same site. Potashner[35] and Nistri[36] have previously shown that the evoked release of ^{3}H-glutamate and acetylcholine from guinea pig cortical slices and from hemisected spinal cord, respectively, is reduced by baclofen. It is tempting to believe that their observations result from an action at the same bicuculline-insensitive GABA receptor.

In conclusion, we have shown the existence of a novel GABA receptor which, when activated, decreases transmitter output. As (−)baclofen is the active isomer not only at this receptor[15] but also in producing neuronal depression[37], its mechanism of action in the therapy of spasticity may indeed be linked with GABA.

Compensatory bilateral changes in dopamine turnover after striatal kainate lesion

Kurt Andersson, Robert Schwarcz & Kjell Fuxe
Department of Histology, Karolinska Institute, Stockholm, Sweden

Diseases of the extrapyramidal systems like Parkinson's disease and Huntington's chorea have been closely associated with the basal ganglia[1,2]. In particular, the prominent symmetrical nigrostriatal dopaminergic systems play an important role in pathogenesis and symptomatology of motor disorders[3–5]. Biochemical[6,7] and electrophysiological[8,9] data indicate a functional relationship between the nigrostriatal pathways on the two brain hemispheres. Unilateral pharmacological manipulations result in short-term changes in contralateral dopamine (DA) release, and surgical lesions on one side lead to long-term alterations in the firing rate of contralateral dopaminergic neurones. We report here the effects of unilateral kainic acid-induced lesions of striatal cell bodies on ipsi- and contralateral striatal DA turnover. We present evidence that morphologically intact dopaminergic neurones on both sides possess compensatory mechanisms which can counteract striatal synaptic asymmetries. Such mechanisms could be responsible at least in part for the maintenance of symmetrical motor behaviour in unilaterally lesioned animals.

After anaesthesia with Nembutal (60 mg per kg, intraperitoneally (i.p.)), male Sprague–Dawley rats (200 g) were positioned in a David Kopf small animal stereotaxic apparatus and kainic acid (1 μg in 0.5 μl phosphate-buffered saline (PBS), *p*H 7.4) was infused unilaterally into the neostriatum (coordinates: 7.9A; 2.6L; 4.8V) as described previously[10]. The animals were killed 2 days to 2 months later by decapitation and the brains rapidly processed according to the Falck–Hillarp technique for the cellular demonstration of catecholamines[11]. The DA stores were measured microfluorimetrically[12]. DA turnover was determined by following DA disappearance after tyrosine hydroxylase inhibition[13]. For this purpose endogenous DA was measured at zero time and at 1 and 2 h after the administration of α-methyltyrosine methyl ester (H44/68, 250 mg per kg, i.p.). Analysis was performed on injected (kainic acid or PBS), contralateral or intact control striata. The medial parts of the caudate nucleus were assessed individually as described previously[14]. To control for the lesion procedure three kainate-injected rats were killed at 2, 10, 35 and 60 days respectively after the lesion, and their brain processed for morphological analysis by light microscopy.

As confirmed in this study, striatal injections of 1 μg kainic acid induce marked degeneration of neuronal cell bodies throughout the nucleus caudatus, nucleus accumbens and piriform cortex and in parts of the globus pallidus and the part of the neocortex overlying the injected striatum. Also, in accordance with recent immunohistochemical and histological findings, dopaminergic nerve terminals appear to be spared by the lesion with the exception of a small area of nonspecific damage around the needle track[14,15]. No morphological changes could be detected on the contralateral striatum.

Two days after kainic acid injection, DA levels and DA turnover in the medial part of the caudate nucleus were

Table 1 Effects of striatal kainic acid injection on DA levels in medial part of caudate nucleus

Days after treatment	Ipsilateral (%)	Contralateral (%)	Normals (%)
	Kainic acid injected		
2	130 ± 8*(4)	110 ± 6(4)	100 ± 7(4)
10	118 ± 9	116 ± 9	100 ± 3
35	146 ± 12**†	106 ± 4	100 ± 3†(4)
	PBS injected

	Kainic acid injected		
60	—	124 ± 4**	100 ± 4

Kainic acid (1 μg dissolved in 0.5 μl saline) was injected unilaterally in normal male rats 2, 10, 35 or 60 days before killing. PBS (0.5 μl) was injected unilaterally after 35 days. Normal male rats served as controls. Animals were killed by decapitation and the caudate nucleus was taken for histochemical analysis of the DA levels[13]. In the turnover experiments H44/68 (250 mg per kg, i.p.) was injected 1 h or 2 h before decapitation[12]. In some cases at the 35 day time point the entire ipsilateral caudate was taken for biochemical analysis. DA levels are expressed as % of control animals, means ± s.e.m. In the biochemical analysis 100% DA = 8,291 ± 279 ng per mg tissue. The fluorescence values obtained in the quantitative microfluorimetrical analysis are given in arbitrary fluorescence units. $n = 6$ if not otherwise noted within parentheses. Statistical analysis according to Mann–Whitney U-test (60 day point) or Wilcoxon: one-way classification, treatment versus control (2, 10 and 35 days treatment). * $P < 0.05$; ** $P < 0.01$. The measurements were made at around level A8500 according to König and Klippel[29].

† Biochemical analysis performed on the whole ipsilateral caudate after killing at 35 days.

0028–0836/80/010094—03$01.00

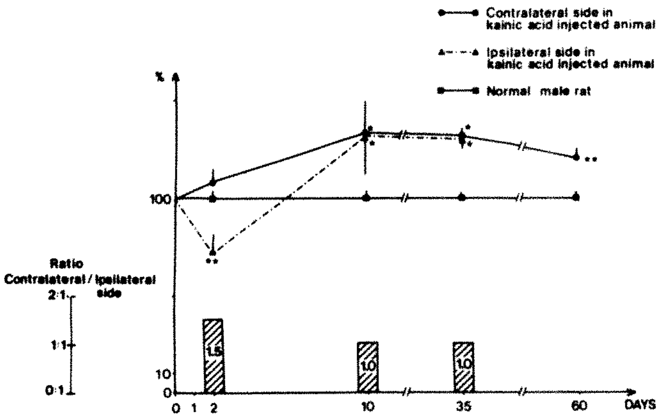

Fig. 1 DA turnover changes in ipsi- and contralateral striata at various times after kainate injection. Data represent values in the medial part of the caudate nucleus 2 h after H44/68 treatment. Values below 100% indicate increased DA turnover, and vice versa. Original data are listed in Tables 1 and 2. Vertical bars indicate the ratios of H44/68-induced DA disappearance between contra- and ipsilateral striata. Statistical analysis according to Wilcoxon: one-way classification, treatment versus control. ★ $P<0.05$; ★★ $P<0.01$.

increased significantly on the injected side as compared to contralateral or control values (Tables 1 and 2). This increase, synchronous with increased tyrosine hydroxylase activity, increased L-dopa accumulation after dopa-decarboxylase inhibition[10,14] and contralateral turning of the lesioned animal[10], seems to reflect a functional response of the dopaminergic nerve terminal to an indirect intrastriatal DA release caused by kainic acid[16] and/or to the loss of inhibitory striatonigral feedback mechanisms after degeneration of striatal neurones[17,18].

By 10 days after the lesion, the increase in DA levels is not as large as 2 days post-injection or has disappeared (Table 1). The DA turnover is now reduced on the lesioned and contralateral side when compared to uninjected control striata (Table 2). The decrements in DA turnover also extend to the central part of the caudate nucleus (level A 8500 according to König and Klippel[29]; L: 2.0 and V extending from +2.0 to 0.0) and to other brain areas rich in dopaminergic nerve terminals like the nucleus accumbens and to a lesser degree the tuberculum olfactorium (data not shown). At 35 days post-lesion significant increases of DA levels were found in the caudatus of the ipsi- and contralateral side; at 60 days significant increases in DA levels were observed in the medial caudate. DA turnover decreases on the contralateral side remain significant at 35 and 60 days after the lesion. At 35 days the biochemical analysis of the entire ipsilateral caudatus still showed reduced DA turnover. Note that injections of PBS-saline into the caudate nucleus did not produce any changes in DA levels and turnover as illustrated in Table 2 for the 35-day post-lesion time point.

At 2 to 3 days after the lesion animals change the direction of spontaneous rotation and start turning towards the lesioned side[10]. Because of the concomitant general hypoactivity of the animals no quantitative evaluation of this turning behaviour (less than one full turn in 5 min) has been performed to date. However, the ipsilateral preference at this stage can be easily observed and the circling strongly accentuated by the administration of dopaminergic drugs[19]. At 5 to 8 days after the lesion the rats stop rotating spontaneously. Figure 1 shows the DA turnover changes at various times after a unilateral striatal kainic acid lesion. Turnover ratios between injected and contralateral striata approach 1.0 at a time when motor asymmetry subsides. Symmetry in striatal DA turnover may therefore contribute to motor symmetry and represent a valid neurochemical marker for the degree of symmetry of motor behaviour in the rat.

The anatomical pathways and biochemical relay systems by which the relevant information is transferred from the lesioned to the contralateral hemisphere are a matter for speculation. Connections within the basal ganglia and bilateral projections from the motor cortex to the caudate nucleus may provide the brain with a network of cross-linkages by which fluctuations in one nigrostriatal system may trigger alterations in contralateral DA turnover[20,21]. However, little is known about the biochemical mechanisms associated with this information flow. Dendritic release of DA in the substantia nigra[22–24] may be involved in this process. It has been shown recently that unilateral nigral DA release can inhibit dendritic DA release in the contralateral substantia nigra while simultaneously increasing contralateral striatal DA release[6].

Table 2 Effects of striatal kainic acid injection on DA turnover in medial part of caudate nucleus

Experiments were performed as detailed in Table 1. Values for DA turnover are given as % of levels at zero time. Statistical comparisons were always made with the respective normal group. * $P<0.05$; ** $P<0.01$.

† Biochemical analysis performed on the whole ipsilateral caudate after killing at 35 days.

Circling in the rat has commonly been associated with dopaminergic receptor mechanisms[25]. Striatal postsynaptic DA-sensitive adenylate cyclase activity and dopaminergic haloperidol or spiperone binding sites decrease by 85% and 40% respectively, by 2 to 6 days after striatal kainate lesions[26,27]. Receptor loss, which can be demonstrated up to 12 months after kainic acid lesions[28], is due to a reduction in the number of binding sites rather than to affinity changes and no alterations can be demonstrated on the contralateral side. Postsynaptic parameters therefore do not seem to contribute significantly to the cessation of spontaneous turning behaviour at 5 to 8 days after the lesion. In contrast, our present data indicate that rotation in the rat can be regulated at the presynaptic level. It seems likely that compensatory changes in striatal DA turnover represent one of the mechanisms by which rats can maintain symmetrical postures in spite of a drastic unilateral striatal impairment. Clearly this mechanism can only partly explain the return of symmetry, since DA receptor loss exists on the operated side and DA release still occurs on the contralateral side. However, it is conceivable that close scrutiny of origin and regulation of this endogenous adaptational process may contribute significantly to our understanding of human movement disorders.

Selective conversion of β-endorphin into peptides related to γ- and α-endorphin

J. P. H. Burbach, J. G. Loeber, J. Verhoef, V. M. Wiegant, E. R. de Kloet & D. de Wied

Rudolf Magnus Institute for Pharmacology, Medical Faculty, University of Utrecht, Vondellaan 6, 3521 GD Utrecht, The Netherlands

β-Endorphin (β-LPH$_{61-91}$) is a well known endogenous opioid ligand. It and related peptides have recently been implicated in the control of adaptive behaviour. Smaller β-endorphin fragments appeared to be more active moieties than the parent molecule in a number of behavioural situations[1]. Their effects seemed to occur independently of interaction with opiate receptor sites in the brain. Moreover, elimination of the opiate-like properties of γ-endorphin (β-LPH$_{61-77}$) by removing the N-terminal amino acid yielded des-tyrosine-γ-endorphin (β-LPH$_{62-77}$, dTγE) which had greater behavioural activity than γ-endorphin[2,3]. The CNS effects of dTγE resembled those of neuroleptic drugs in several test systems. α-Endorphin (β-LPH$_{61-76}$) exerted effects opposite to those of dTγE and in some aspects its activity was comparable to that of psychostimulant drugs[4]. This opposition of effects suggests that a balance between γ- and α-type endorphins is involved in the control of brain function[5]. We report here that either γ-endorphin and dTγE or α-endorphin and des-tyrosine-α-endorphin (β-LPH$_{62-76}$, dTαE) can be formed preferentially from β-endorphin by enzymes associated with an enriched synaptosomal plasma membrane fraction from brain. It is suggested that these enzymes have a role in brain homeostatic mechanisms by regulating the generation of these substances.

Synaptosomal plasma membrane (SPM) preparations from rat brain were obtained by differential centrifugation (see legend to Fig. 1). β-Endorphin (20 nmol) was incubated with the SPM preparation (3.5 mg protein) at 37 °C for 30 min in 1 ml saline buffered with either 25 mM sodium phosphate (*p*H 7.4, 6.7 and 5.9) or 25 mM sodium acetate (*p*H 5.0). The reaction was stopped by heating the suspension at 95 °C for 10 min and the membranes were removed by centrifugation. The supernatant was subjected to high-pressure liquid chromatography (HPLC) fractionation and the peptide-containing fractions were collected. The products were identified by combined application of HPLC and radioimmunoassay (RIA). The HPLC system was able to separate very similar β-endorphin fragments in a highly reproducible manner (Fig. 1). Analysis of their immunoreactivity provided an additional criterion for the identity of peptides cross-reacting in the respective RIA systems.

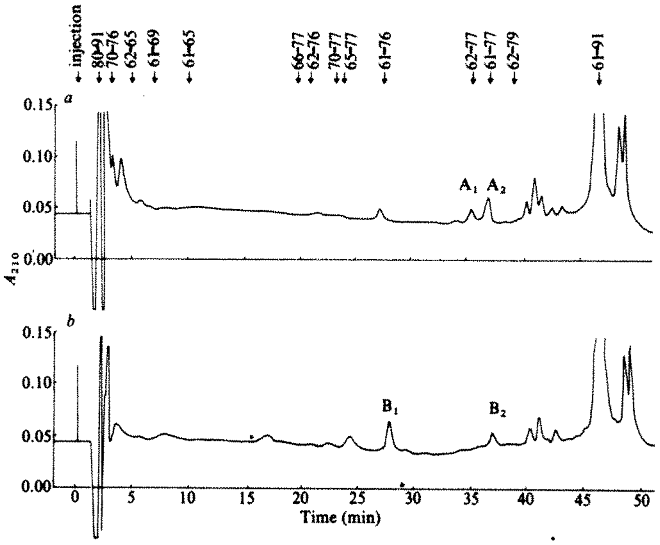

Fig. 1 HPLC fractionation of peptides formed by conversion of β-endorphin by enzymes associated with a SPM preparation. A 10% (w/v) homogenate of rat forebrain in 0.32 M sucrose was centrifuged at 1,000g_{av} for 10 min. The supernatant was centrifuged at 10,000g_{av} for 20 min and the resulting crude mitochondrial–synaptosomal fraction was lysed in distilled water (5 ml per g tissue) at 0 °C for 30 min. The supernatant obtained by centrifugation of the suspension at 10,000g_{av} for 20 min contained the synaptosomal plasma membranes. The membranes were washed and stored at −20 °C. Incubations were carried out as described in the text. Samples (700–800 μl) were subjected to HPLC fractionation on a μBondapak C_{18} reversed-phase column (0.39×30 cm) eluted with a concave gradient of 10 mM ammonium acetate, *p*H 4.15 (X) and methanol, containing 1.5 ml l^{-1} acetic acid (Y). Initial conditions: $X:Y=70:30$, final conditions: $X:Y=25:75$. The flow rate was 2 ml min^{-1}. HPLC chromatograms of peptide mixtures were obtained after incubation of β-endorphin at *a*, *p*H 6.7 and *b*, *p*H 5.9. The retention times of a series of reference peptides are indicated at the top. Fractions A_1 and A_2 contained dTγE and γ-endorphin respectively; fractions B_1 and B_2 contained α-endorphin and γ-endorphin respectively.

Briefly, the specificities of the antisera were as follows. For the anti-α-endorphin serum, the percentage cross-reaction compared to α-endorphin was 110% for dTαE, 2% for γ-endorphin, 5% for dTγE, 1% for β-endorphin and 0.13% for methionine enkephalin. For the anti-γ-endorphin serum, dTγE cross-reacted 120%, α-endorphin 8%, dTαE 0.6%, β-endorphin 4% and methionine enkaphalin 0.02%. Details of the RIA systems have been given elsewhere[6].

β-Endorphin was digested by enzymes present in the SPM preparation. HPLC fractionation of the digests revealed the presence of β-endorphin fragments with retention times identical to those of dTγE, γ-endorphin and α-endorphin in the HPLC system (Fig. 1). Their identity was confirmed by analysis of the immunoreactivity in the appropriate RIA systems (Fig. 2). Essentially the same results were obtained when β-endorphin was incubated with a purified SPM preparation obtained by sucrose density centrifugation as described by Terenius[7].

RIA of β-endorphin fragments collected during HPLC fractionation of the digests enabled us to quantitate α-endorphin, dTαE, γ-endorphin and dTγE. The accumulation of fragments was highly *p*H-dependent. The largest amounts of α-endorphin

0028–0836/80/010096—02$01.00

and small amounts of γ-endorphin and dTγE were detected in fractions obtained at *p*H 5.9. The same *p*H seemed to be optimal for the accumulation of dTαE, a minor component of the digests. Increasing the *p*H to 6.7 completely reversed the ratio of α- to γ-type fragments: α-endorphin decreased whereas there was a marked increase in both γ-endorphin and dTγE (Fig. 3).

Austen and Smyth, using β-endorphin with the N-terminal tyrosine residue labelled with ^{125}I have demonstrated the production of γ-endorphin at *p*H 7.4 and of α-endorphin at *p*H 5.0 by brain membranes; most of the methionine-enkephalin was also found at *p*H 5.0 (refs 8, 9). Their experiments were performed in the presence of bacitracin so as to protect the peptide against release of the labelled amino acid residue. The present studies were designed to detect the formation of des-tyrosine endorphins and to extend previous observations to synaptosomal plasma membranes.

Peptide fragments accumulate as a result of both formation and degradation. It has been suggested that initial steps in the degradation of β-endorphin by brain extracts involves cleavages by several endopeptidases, followed by rapid breakdown of the resulting intermediates to free amino acids[10,11]. The present results show that an enriched synaptosomal plasma membrane preparation contains an enzyme system for the conversion of β-endorphin into γ-endorphin, dTγE, α-endorphin and dTαE. Either dTγE and γ-endorphin or α-endorphin accumulated preferentially depending on the *p*H. Thus, the *p*H appears to determine whether the breakdown of γ-endorphin and dTγE or that of α-endorphin is the rate-limiting step in the enzymatic conversion of β-endorphin. As a consequence of the mechanism of degradation rather low amounts of the accumulated peptides were detected.

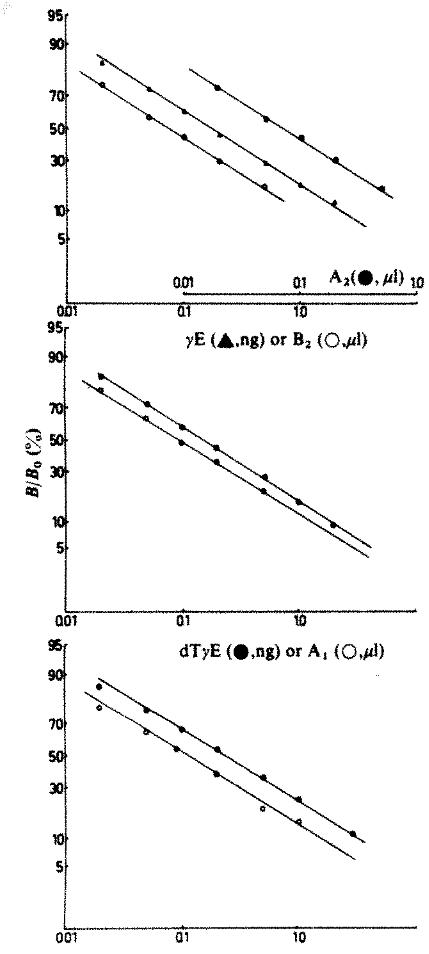

Fig. 2 Immunological activity of peptides in fractions A_1, A_2, B_1 and B_2 (see Fig. 1 legend) as tested in radioimmunoassay systems for dTγE, γ-endorphin, α-endorphin and γ-endorphin, respectively. Fractions of the HPLC eluate containing the β-endorphin fragments were collected and methanol was evaporated *in vacuo* at 60 °C. Aliquots of the residual solution (indicated as μl) were subjected to the appropriate RIA. Ordinate shows final fraction bound as a percentage of initial bound.

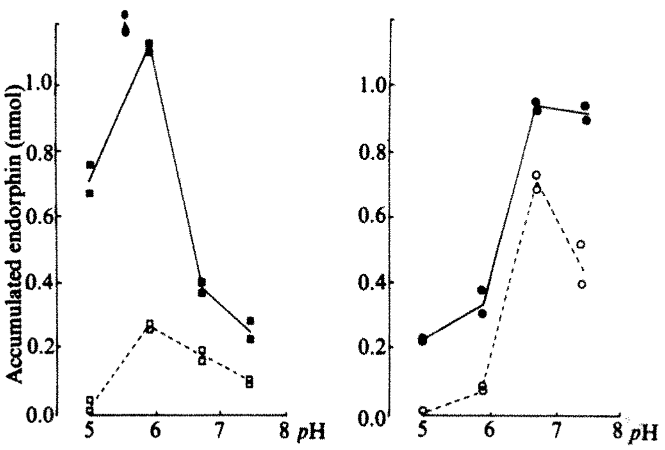

Fig. 3 *p*H dependence of the accumulation of α-endorphin (■), dTαE (□), γ-endorphin (●) and dTγE (○) upon incubation of β-endorphin with a SPM preparation. Digests were prepared and fractionated as described in the text and in the legend to Fig. 1. Fractions containing the individual β-endorphin fragments were collected during HPLC fractionation and methanol was removed *in vacuo* at 60 °C. Peptides contained in the residual solution were quantitated in the RIA systems for the various β-endorphin fragments. Values were obtained from two separate experiments.

Recently, using HPLC and RIA we have detected des-tyrosine-endorphins in biological material in addition to α-, γ- and β-endorphin. dTγE and dTαE are present in rat pituitary[6], in rat brain and in human cerebrospinal fluid (J. P. H. B. *et al.*, in preparation). Together with the present study this observation supports our view that des-tyrosine-endorphins are endogenous peptides and are formed by selective cleavage of β-endorphin.

β-Endorphin fragments may be factors involved in behavioural adaption. According to the hypothesis put forward by De Wied[5], normal brain functioning would require a balance between dTγE or a peptide related to it and α-type endorphins. Consequently, the enzyme system acting in our experiments may provide a regulatory mechanism for the turnover of the two ligands. The preferential formation of dTγE and γ-endorphin or α-endorphin over a narrow, near physiological *p*H range shows that the enzyme system can be modulated. The experimental *p*H changes may have mimicked physiological processes leading to this modulation. Thus, by showing the formation of dTγE, γ-endorphin and α-endorphin by enzymes present in an enriched synaptosomal plasma membrane fraction, the experiments described here may have provided a biochemical basis for the hormonal regulation of adaptive behaviour.

We thank Dr H. M. Greven (Organon International B.V.) for the gift of synthetic human β-endorphin and related peptides.

Parallel pathways for transduction of chemotactic signals in *Escherichia coli*

Gerald L. Hazelbauer & Peter Engström

The Membrane Group, The Wallenberg Laboratory,
University of Uppsala, S-752 37 Uppsala, Sweden

Bacteria respond transiently to tactic stimuli[1], which indicates that cells adapt to new levels of stimulation. Receptors[2,3] send signals to a tumble regulator that controls the balance between directions of flagellar rotation[4], creating a pattern of swimming and tumbling that results in taxis[5]. In *Escherichia coli*, mutations in *tsr* and *tar* affect receptor–regulator linkages, eliminating responses mediated by two different groups of receptors[6–9]. Sensitivity to most sugars is not reduced by either mutation but observations that *tsr–tar* double mutants do not respond to spatial gradients of any compound led to the suggestion that the *tsr* and *tar* products together provide a necessary final step in transduction from all receptors[7,8]. Another class of pleiotropic taxis mutations, *trg*[10–13], causes defective transduction from only two receptors, those for galactose and ribose. We were therefore interested in determining whether the *trg* function represented an early stage of transduction or whether it was analogous to the *tsr* and *tar* functions. We have examined the sensitivity of *tsr* and *tar* double mutants to temporal gradients, prompted by a report that such gradients of galactose or ribose evoke responses in those strains[14]. We report here that *tsr–tar* double mutants were sensitive to stimulation by compounds to which both single mutants respond but were drastically defective in adaptation to these stimuli. We suggest there are at least four parallel, single-component pathways for transduction of tactic signals, from the Tsr, Tar, Trg and enzyme II groups of receptors.

We used four *tsr–tar* double mutants (see Table 1 legend) and confirmed that they tumble very infrequently[7–9]. *tsr–tar* cells tethered to a glass surface spun only in the counterclockwise, smooth-swimming direction, in contrast to wild-type cells which frequently reverse their direction of rotation. However, undisturbed cells initiated reversals at times ranging from 5 to 40 min after tethering and subsequently behaved much like wild-type cells. We believe the delayed onset of a normal rotational pattern results from the adaptational defect of these mutants documented below. Lack of tumbling by swimming cells and absence of clockwise rotation by tethered cells would then be a reflection of extended times necesseary for adaptation to stimuli received during prior manipulation (such as changes in temperature or concentration of O_2 or K^+ ion).

After tethered *tsr-tar* cells had begun to exhibit normal rotational patterns, we applied maximal temporal stimuli, gradients from 0 to 10 mM, of the compounds listed in Table 1. Compounds inactive in either *tsr* or *tar* mutants were predictably inactive in the double mutants. Two amino acids, asparagine and cysteine, which evoke significant responses in both *tsr* and *tar* mutants[6], did not stimulate a double mutant. This is consistent with the notion that receptors for these compounds interact with both the *tsr* and *tar* transductional pathways and one or the other must be functional for a response[7,8]. In contrast, *tsr–tar* double mutants responded to sugars in the same way as wild-type cells, by complete suppression of tumble-mode rotation. However, adaptation was significantly delayed after maximal stimuli of sugars recognised by enzyme II receptors[3,15] and did not occur even after prolonged times for those recognised by *trg*-related receptors. Delayed adaptation did occur after moderate stimuli of allose and fucose, non-metabolisable analogues of ribose and galactose, respectively (Fig. 1). Behaviour of a *tsr–tar* double mutant lacking the galactose receptor as the result of an *mglB* mutation[16] (Table 1) demonstrates that responses observed in *tsr–tar* double mutants require the appropriate chemoreceptor. In addition, it eliminates the possibility that responses to enzyme II sugars are caused solely by low level contamination with galactose or glucose, which are recognised at micromolar concentrations by the galactose receptor.

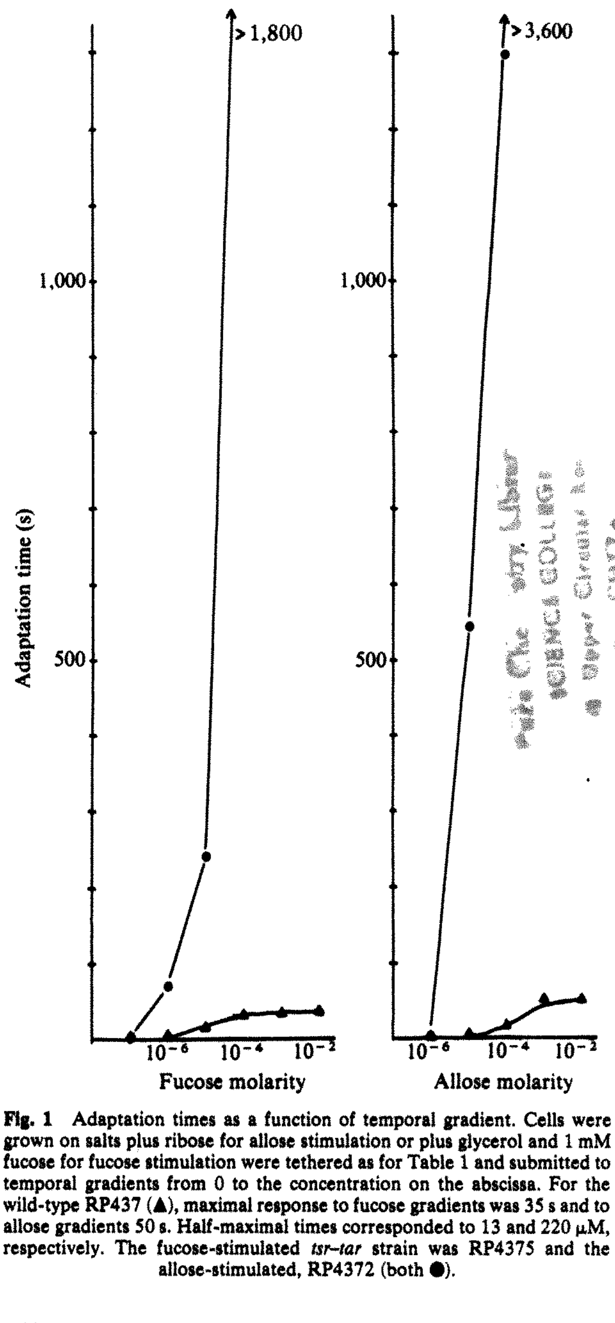

Fig. 1 Adaptation times as a function of temporal gradient. Cells were grown on salts plus ribose for allose stimulation or plus glycerol and 1 mM fucose for fucose stimulation were tethered as for Table 1 and submitted to temporal gradients from 0 to the concentration on the abscissa. For the wild-type RP437 (▲), maximal response to fucose gradients was 35 s and to allose gradients 50 s. Half-maximal times corresponded to 13 and 220 μM, respectively. The fucose-stimulated *tsr–tar* strain was RP4375 and the allose-stimulated, RP4372 (both ●).

When an attractant recognised by an enzyme II receptor was washed away from adapted *tsr–tar* cells, reversals between clockwise and counterclockwise rotation ensued at high frequency for periods of the order of a minute. Wild-type cells stimulated by 10 mM to 0 gradients of those sugars exhibit only a few seconds of clockwise rotation. Thus, it seems that *tsr–tar* double mutants are also sensitive to unfavourable stimuli mediated by sugar receptors and, as in the case of favourable stimuli, are defective in adaptation.

A *trg* null mutation[12] was introduced into the four *tsr–tar* double mutants. We found that tethered cells of *tsr–tar–trg* triple mutants rotated exclusively in the smooth-swimming direction and, in contrast to the double mutants, never showed a relaxation to normal alternating rotational behaviour. We believe this phenotype to be a more drastic extension of the adaptational defect of the double mutants, implying that the *trg* product is involved in adaptation as well as transduction.

0028-0836/80/010098—03$01.00

Table 1 Adaptation times of tethered cells to maximal temporal stimuli

Attractant	Receptor	Transducer	Adaptation time (s) WT	WT *mgl*B	*tsr tar*	*tsr tar mgl*B	Ratio *tsr tar*/WT
Galactose	GBP	Trg	30	ND	>1,800	ND	>60
Fucose	GBP	Trg	33	0	>1,800	9	>55
Ribose	RBP	Trg	50	ND	>1,800	ND	>36
Allose	RBP	Trg	48	50	>1,800	>1,800	>37
Glucose*	enz $\text{II}^{\text{glu}*}$	Unident.	ND	52	>1,800	157	3
Fructose	enz II^{fru}	Unident.	41	32	540	390	12
Sorbitol	enz II^{sbl}	Unident.	55	15	642	353	24
N-acetylglucosamine	enz II^{NAG}	Unident.	72	55	480	239	4
Asparate	Unident.	Tar	258	ND	60	0	0
α-methylaspartate	Unident.	Tar	221	ND	26	0	0
Serine	Unident. (2)	Tsr + Tar	790	720	49	18	0.02
Asparagine	Unident.	Tsr + Tar	ND	258	ND	0	0
Cysteine	Unident.	Tsr + Tar	ND	330	ND	0	0

Cells were grown at 37 °C in minimal salts[10] plus ribose (*mgl*B) or ribose and 1 mM fucose (*mgl*B^+). No special measures were taken to induce maximal levels of enzymes II. Flagella were sheared, cells tethered by antiflagella serum, stimulated by temporal gradients at 37 °C and observed on videotape recordings as described elsewhere[11]. Adaptation time for a given cell was the time after stimulation by an attractant when the first complete clockwise rotation occurred. Values given are mean times for 10–20 cells in one or usually two experiments. Standard deviations were 20–30% for short (~60 s) times and somewhat less for longer times. *tsr–tar* double mutants often exhibited poor motility and thus could be tethered without shearing. Such cells initiated normal rotational behaviour (see text) sooner than sheared cells. A change of buffer surrounding tethered cells results in an inhibition of clockwise rotation for an average of 5–10 s in wild-type cells and 30–150 s in *tsr–tar* cells, the values varying for different preparations of tethered cells. These background responses have been subtracted from the raw data to yield the values given. As in the case of *che*X mutants[19], the double mutants had a tendency to lose the ability to rotate clockwise after extended times (> 1 h) in chemotaxis buffer. The wild-type (WT) strain was RP437 (ref. 21) and the *tsr–tar* mutant RP4375 (*tsr* 2·3·4 *tar* 52Δ1). Similar behaviour was observed for RP4372 (*tsr* 518 *tar* 52Δ1), RP4373 (*tsr* 518 *tar* 1) and RP 4376 (*tsr* 2·3·4 *tar* 1). An *mgl*B::Tn*5* mutation (S. Harayama and G.L.H., unpublished) was introduced by transduction, and the absence of the gene product confirmed by SDS-polyacrylamide gel electrophoresis[22]. *trg*2::Tn*10* (ref. 12) was introduced into each *tsr–tar* double mutant by transduction and the presence of the mutation confirmed by transduction of the Tc^r, Trg character back into a wild-type strain. All compounds were obtained from commercial sources and used without further purification. Ratios of mutant to WT response were calculated using values for *mgl*B derivatives where adaptation times of those derivatives were shorter than the parent strain, indicating that the sugar might contain contaminating glucose or galactose. GBP, galactose–glucose-binding protein; RBP, ribose-binding protein; MBP, maltose-binding protein; Unident., unidentified; ND, not determined.

* Glucose is recognised by three receptors, GBP, enz II^{glu} and enz II^{man}. There is very little enz II^{man} receptor activity in these strains.

The relationship between transduction and adaptation merits further discussion. The *tsr* and *tar* products, phenotypically identified as transducers, are directly involved in adaptation to the stimuli they transduce[14]. Adapatation is correlated with carboxylmethylation or demethylation of the two products, termed methyl-accepting protein (MCP) I and II, respectively[7,8]. Recently, an independent MCP III was shown to be methylated on stimulation by compounds recognised by galactose and ribose receptors[13]. MCP III is not methylated in *trg* mutants and may well be the *trg* product. These observations correlate well with our conclusions that *trg* represents an independent transducer that is also involved in adaptation.

tsr–tar double mutants lack only two transducer/MCPs and exhibit correspondingly limited defects in tactic sensitivity. However, the mutants are generally defective in adaptation. Interestingly, *tsr* and *tar* single mutants swim smoothly for longer times than wild-type cells after temporal stimulation by active compounds[7]. The extended times were considered to be enhanced responses[7]; we suggest instead that they indicate moderately defective adaptation. Modest extensions of adaptation times may result in increased accumulations in spatial gradients[6,7], but mutants exhibiting very long adaptation times do not accumulate at all (ref. 7 and the present study). It is striking that *tsr–tar* mutants are as defective in adaptation to maximal stimuli of *trg*-related compounds as are cells unable to methylate because of methionine starvation[17] or a defective methyltransferase[18,19], even though methionine, the transferase and the appropriate transducer/MCP are present.

The extended adaptation times of *tsr–tar* double mutants pose the question of whether methylation levels are correspondingly increased, as might be expected from the correlation of methylation increases and adaptation in wild-type cells[20]. This does not seem to be the case. Double mutants stimulated by gradients of fucose (Fig. 2) or allose (data not shown) exhibit very little detectable methylation, whether the stimulus is one to which the mutant adapts after extended times or one to which it does not adapt in the time of the experiment (see Fig. 1). Basal levels of MCP III methylation in *tsr–tar* mutants are low[13] and adaptation by wild-type strains to maximal *trg*-transduced stimuli corresponds to a 50% increase in MCP III methylation. Thus, it is not possible to conclude from Fig. 2 whether both adapatation and MCP III methylation simply proceed slowly in *tsr–tar* mutants or whether adaptation occurs slowly by a process independent of methylation.

The observation that *tsr–tar* double mutants respond to temporal gradients of sugars demonstrates that the *tsr* and *tar* products together do not transduce signals from all receptors[7–9]. Identification of defective adaptation rather than defective response as the basis for the inability of double mutants to accumulate in spatial gradients of sugars removes the remaining

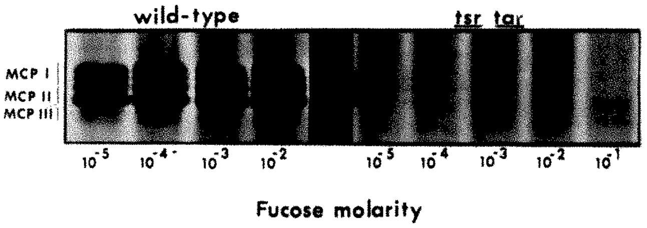

Fig. 2 Methylation patterns of wild-type cells and a *tsr–tar* mutant after stimulation by fucose. Cells were grown in salts plus ribose and 1 mM fucose, washed, resuspended, exposed to [*Me*-^{3}H] methionine (12 Ci mmol^{-1}, Amersham), subjected to temporal gradients from 0 to the concentration indicated and collected 30 min after stimulation essentially as described previously[7]. Approximately 10^8 cells were subjected to electrophoresis on an SDS-10% polyacrylamide gel. The gel was prepared for fluorography and exposed to X-ray film[23]. Only the section of the autoradiogram including the area of known MCPs (apparent molecular weights 56,000–65,000 (ref. 7)) is shown. Wild-type and *tsr–tar* are as in Table 1. The range of methylated bands that constitute MCPs I and II are indicated based on the scheme in ref. 7. We have observed that MCP III includes at least two methylated bands (P.E. and G.L.H., in preparation).

barrier to postulating that the *tsr*, *tar* and *trg* products function as analogous, independent transducers. All data now suggest that the link between any receptor and the tumble regulator is a single transducer protein and that the protein is an MCP, methylated during adapatation to the stimuli it transduces. No observations remain that require postulation of multi-step linkages between receptor and regulator[1,3,13,14].

We suggest that there is at least one additional transducer/MCP, serving enzyme II receptors, as *tsr*, *tar* or *trg* mutations do not eliminate responses to enzyme II sugars[9,11,13]. Also, *trg*-transduced stimuli can be distinguished from enzyme II-mediated stimuli by the inability of *tsr–tar* double mutants to adapt to maximal levels of *trg* stimuli (Table 1).

This work was supported by grants from the Swedish Natural Sciences Research Council. We thank B. Berneholm for technical assistance, Dr J. S. Parkinson for sending his collection of *tsr–tar* double mutants, and Dr S. Harayama and R. K. Booth for comments and suggestions.

Translational control of proinsulin synthesis by glucose

Nobuyuki Itoh & Hiroshi Okamoto*

Department of Biochemistry, Toyama Medical and Pharmaceutical University, School of Medicine, Toyama 930-01, Toyama, Japan

Glucose is known to stimulate proinsulin synthesis in pancreatic islets of rats as well as of many other animals[1], but the mechanism involved remains uncertain. If proinsulin induction by glucose is regulated at the transcriptional level, the amount of proinsulin mRNA may be increased by the administration of glucose. Alternatively, if proinsulin induction is regulated at the translational level, the rate of proinsulin synthesis may not be correlated with the amount of proinsulin mRNA. We have now used a proinsulin cDNA hybridisation method to determine the amount of proinsulin mRNA and the subcellular distribution of proinsulin mRNA in rat pancreatic islets. The results suggest that glucose-induced proinsulin synthesis is mainly achieved by enhancing the translation efficiency of proinsulin mRNA pre-existent on the membrane-bound polysome in pancreatic islets.

Proinsulin mRNA was purified from rat B-cell tumours induced with streptozotocin and nicotinamide, and proinsulin cDNA was synthesised using purified proinsulin mRNA as a template[2–4]. The fidelity of the hybridisation reaction with proinsulin mRNA and its cDNA was assessed from the following evidence: (1) the hybridisation occurred within two orders of magnitude, as expected of a pseudo-first order reaction[3]; (2) the experimental $R_0t_{1/2}$ value (2.1×10^{-4}) was in good agreement with the expected value (2.7×10^{-4}) calculated from the $R_0t_{1/2}$ value of the hybridisation with mouse globin mRNA and its cDNA[3]; (3) a sharp thermal denaturation curve of the hybrid with T_m of 74 °C was obtained (data not shown). As shown in Fig. 1*a*, trace amounts of proinsulin mRNA (0.05–0.5 ng) could be measured by hybridisation with proinsulin cDNA. As it is difficult to prepare many islets from rat pancreas, this sensitive hybridisation assay is of particular value. To examine the specificity of the hybridisation reaction, we prepared total RNA from rat pancreatic islets, rat B-cell tumours and rat liver, and examined the hybridisation of proinsulin cDNA with total RNA from these tissues (Fig. 1*b*). From the extent of the hybridisation, the proinsulin mRNA content of total RNA from islets and that from B-cell tumours were determined to be 0.38% and 0.25%, respectively. As the proinsulin mRNA content of total RNA from islets and B-cell tumours determined by the hybridisation method was consistent with that determined by a wheat-germ cell-free translation assay[3–5], it is reasonable to assume that almost all the amount of proinsulin mRNA determined by the hybridisation method was translatable proinsulin mRNA. Total RNA of rat liver did not hybridise with proinsulin cDNA. These results suggest that the hybridisation reaction was highly specific.

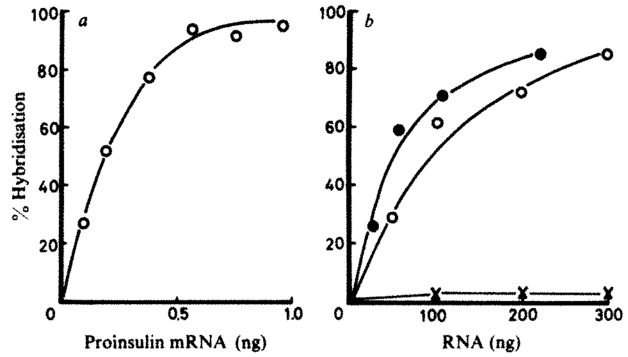

Fig. 1 Quantification of proinsulin mRNA by hybridisation with proinsulin cDNA. ^{3}H-proinsulin cDNA was synthesised using proinsulin mRNA purified from rat B-cell tumours as a template as described previously[3,4]. The hybridisation reaction was carried out at 65 °C for 20 h in a 50-μl reaction mixture (0.5 M NaCl, 25 mM HEPES-NaOH, *p*H 7.3, 1 mM EDTA, 0.1% SDS, 4 μg yeast RNA) after heating at 100 °C for 2 min. The reaction was stopped by adding 0.4 ml of 0.2 M sodium acetate (*p*H 4.5) containing 0.4 M NaCl, 2 mM zinc acetate and 6,000 units of nuclease S_1 (Seikagaku Kogyo), followed by incubation at 37 °C for 1.5 h. After incubation, 200 μg yeast DNA was added to the incubated mixture, and the nuclease S_1-resistant hybrid was precipitated with cold 10% trichloroacetic acid, and collected on a Toyo membrane filter TM-2. The filter was dissolved in 2 ml Cellosolve and the radioactivity was counted in a toluene-based scintillation solution. Total RNA was prepared from rat pancreatic islets, rat B-cell tumours and rat liver with the phenol extraction and LiCl-precipitation procedures[3]. *a*, Hybridisation of purified proinsulin mRNA with ^{3}H-proinsulin cDNA. *b*, Hybridisation of the total RNA from pancreatic islets (●), B-cell tumours (○) and liver (×) with ^{3}H-proinsulin cDNA.

The effects of glucose on proinsulin synthesis in isolated pancreatic islets of rats were examined. When the concentration of glucose in the incubation medium was increased from 2.8 mM to 25 mM, the proinsulin synthesis was greatly stimulated (~10-fold) (Fig. 2*a*) and proinsulin synthesis in the glucose-stimulated islets comprised 53% of the total protein synthesis. In contrast, the non-proinsulin protein synthesis was only slightly stimulated (~1.3-fold). These results suggest that the glucose-stimulation effect on protein synthesis in islets is highly specific to proinsulin synthesis.

In a wheat-germ cell-free system, we found that the amount of proinsulin mRNA in islets as determined by translation assay

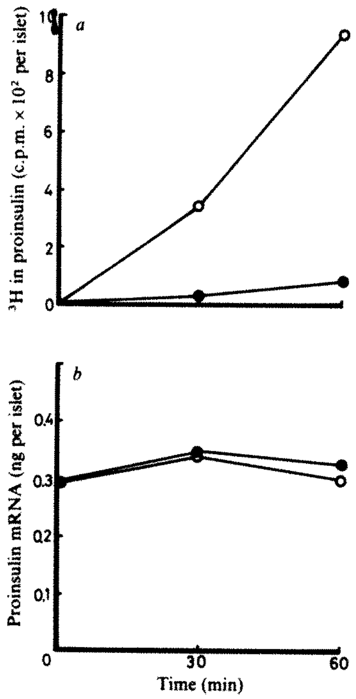

Fig. 2 *a*, Time course of induction of proinsulin synthesis by glucose in pancreatic islets. Pancreatic islets were prepared from male Wistar rats (200–240 g), which had been fasted for 18 h, in mild conditions of collagenase treatment as described previously[6]. Twenty islets were incubated at 37 °C for the indicated time in 125 μl Dulbecco's modified Eagle's medium (without glucose and leucine) containing 10 μCi ^{3}H-leucine (57.4 Ci mmol^{-1}, NEN), 2.8 mM (●) or 25 mM (○) glucose and 20% fetal calf serum (GIBCO). After incubation, the incubated islets were washed three times with 1 ml ice-cold Hank's solution, suspended in 0.2 ml of 60 mM Tris-phosphoric acid (*p*H 6.8) containing 1% SDS, 5% 2-mercaptoethanol and 10% glycerol, and sonicated for 10 s with a microtip of a Kontes ultrasonic cell disruptor. The sonicated material was heated at 100 °C for 2 min. An 80-μl aliquot of the heated sample was submitted to SDS-polyacrylamide (15%) gel electrophoresis (1 × 4 cm)[7]. After electrophoresis, the gel was cut into 1-mm slices and extracted with a Gilson B-100 gel fractionator. The radioactivity of the gel slice was counted in a toluene-based scintillation solution. The amount of newly synthesised proinsulin was calculated by summing ^{3}H-leucine radioactivity of the gel slices corresponding to the proinsulin peak[4,5]. *b*, Time course of proinsulin mRNA level during induction of proinsulin synthesis by glucose in pancreatic islets. Twenty-five islets were incubated at 37 °C for the indicated time in the presence of 2.8 mM (●) or 25 mM (○) glucose as described in Fig. 2*a*, except for addition of 0.2 nmol unlabelled leucine instead of 10 μCi ^{3}H-leucine. The incubated islets were washed once with 1 ml ice-cold Hank's solution and sonicated for 20 s with a microtip of a Kontes ultrasonic cell disruptor in 0.5 ml of 0.1 M Tris-HCl (*p*H 9) containing 10 mM EDTA, 0.1 M dithiothreitol, 2% SDS and 20 μg yeast RNA and an equal volume of a phenol solution (phenol/chloroform/isoamylalcohol 50 : 50 : 2) equilibrated with 0.1 M Tris-HCl (*p*H 9) containing 10 mM EDTA. The emulsion was vigorously shaken at room temperature for 5 min, left on ice for 5 min and centrifuged to separate two phases. The water phase was removed, and the phenol phase was re-extracted with 0.5 ml of 0.1 M Tris-HCl (*p*H 9) containing 10 mM EDTA and 2% SDS. The combined water phases were re-extracted with the phenol solution. Nucleic acid was precipitated by adding 0.1 vol. of 2 M sodium acetate (*p*H 5.5) plus 2.5 vol. of ethanol at −20 °C for 16 h. The precipitate was collected by centrifugation and washed once with 2 ml of cold 75% ethanol. Aliquots of the nucleic acid were used for quantification of proinsulin mRNA by hybridisation with proinsulin cDNA.

remained unchanged during the period of proinsulin induction by glucose for up to 60 min[4,5]. In the present paper, we have confirmed our previous result by the hybridisation method. The amount of proinsulin mRNA in the glucose-stimulated (25 mM glucose) or -unstimulated (2.8 mM glucose) islets remained unchanged during the period of proinsulin induction for up to 60 min (Fig. 2*b*).

To examine the subcellular localisation of proinsulin mRNA in the glucose-stimulated or -unstimulated islets, we prepared subcellular fractions from the islets. After pancreatic islets were incubated in a medium containing 2.8 mM or 25 mM glucose for 60 min at 37 °C, the islets were homogenised with rat liver as carrier, and membrane-bound polysome, free polysome and post-polysomal supernatant fractions were prepared. RNA was extracted from the subcellular fractions. Aliquots of the extracted RNA were used for quantification of proinsulin mRNA (Table 1). Recoveries of proinsulin mRNA in the membrane-bound polysome fractions were 58% for glucose-stimulated and 40% for unstimulated islets. However, a significant amount of proinsulin mRNA was also detected in the post-polysomal supernatant fraction; this was more marked in the unstimulated islets.

In some eukaryotic cells, some mRNAs have been shown to be present in a post-polysomal supernatant fraction as messenger ribonucleoprotein (mRNP; actin mRNP[9], histone mRNP[10], globin mRNP[11], albumin mRNP[12]). As it has been suggested that the mRNP may be involved in the regulation of the mRNA translation[9,12], it would be interesting to determine whether proinsulin mRNA is present in the post-polysomal supernatant fraction complexed with protein to form mRNP. To characterise the form of proinsulin mRNA present in the supernatant fraction, the supernatant was fractionated by sucrose gradient centrifugation and proinsulin mRNA sequences in each gradient fraction were quantified with proinsulin cDNA. The sedimentation profile of proinsulin mRNA sequences in the supernatant fraction exhibited an almost single major peak in the region of approximately 9S, which corresponds to the sedimentation value of intact proinsulin mRNA free from protein (Fig. 3)[3]. This suggests that proinsulin mRNA detected in the post-polysomal supernatant exists as an intact and free form.

The present experiment with isolated pancreatic islets of rats shows that the amount of proinsulin mRNA remains unchanged during the induction of proinsulin synthesis by glucose. Thus glucose regulates proinsulin synthesis at the translation level (translational control). Proinsulin mRNA, and mRNAs coding for other secretory proteins, have been shown to be translated on the membrane-bound polysome[13]. From the subcellular distribution of proinsulin mRNA in the glucose-stimulated or

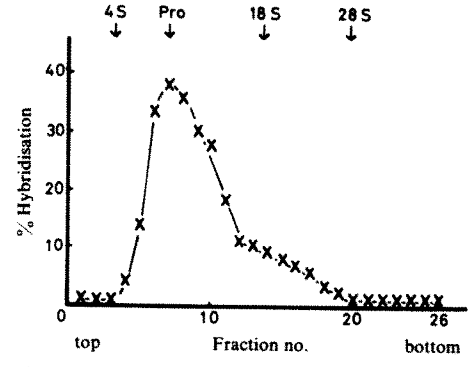

Fig. 3 Sucrose gradient sedimentation profile of proinsulin mRNA sequences in post-polysomal supernatant. After concentration with a Toyo membrane filter UK-50, an aliquot of the post-polysomal supernatant fraction of glucose-unstimulated islets was applied on a linear 15–30% sucrose gradient made in 10 mM Tris-HCl (*p*H 7.6) containing 0.5 M KCl, 2 mM EDTA and 100 μg ml^{-1} heparin. Centrifugation was performed at 60,000 r.p.m. at 0 °C for 3.5 h in a Beckman SW 60 Ti rotor. The gradient was fractionated with a Buchler Instrument Densi-Flow. From each fraction, RNA was extracted and used for quantification of proinsulin mRNA by hybridisation with proinsulin cDNA. Arrows indicated relative sedimentation of: 4S, rat liver tRNA; Pro, proinsulin mRNA; 18S, rat liver 18S rRNA; 28S, rat liver 28S rRNA.

Table 1 Subcellular distribution of proinsulin mRNA in pancreatic islets

Glucose	Membrane-bound polysome	Free polysome	Post-polysomal supernatant
Expt 1			
2.8 mM	0.099 (39.4)	0.033 (13.1)	0.119 (47.5)
25 mM	0.136 (57.9)	0.028 (11.9)	0.071 (30.2)
Expt 2			
2.8 mM	0.109 (41.4)	0.031 (11.8)	0.123 (46.8)
25 mM	0.145 (58.4)	0.036 (14.5)	0.067 (27.1)

One hundred and fifty islets were incubated at 37 °C for 60 min in the presence of 2.8 mM or 25 mM glucose as described in Fig. 2*a*, except for addition of 0.2 nmol unlabelled leucine instead of 10 μCi ^{3}H-leucine. The incubated islets were washed once with 1 ml ice-cold Hank's solution, added to 0.1 g wet weight of rat liver as carrier and homogenised at 0 °C with 10 strokes of a motor-driven glass–Teflon Potter–Elvehjem homogeniser in 3.9 ml of 250 mM sucrose containing 10 mM HEPES-KOH (*p*H 7.4), 75 mM KCl, 5 mM $MgCl_2$, 3 mM glutathione and 0.5% diethyl pyrocarbonate. The homogenate was centrifuged at 2,000 r.p.m. at 0 °C for 10 min in a Sorvall HB-4 rotor. After addition of heparin (100 μg ml^{-1}), membrane-bound polysome, free polysome and post-polysomal supernatant were prepared from the post-nuclear supernatant essentially according to the same methods as of Ramsey and Steele[8] and Bag and Sarkar[9]. Each subcellular fraction was precipitated with cold 10% trichloroacetic acid and washed with cold 75% ethanol and diethyl ether. Nucleic acid was extracted from the trichloroacetic acid-precipitate as described in Fig. 2*b*. Aliquots of the nucleic acids were used for quantification of proinsulin mRNA by hybridisation with proinsulin cDNA. Values are expressed as ng proinsulin mRNA per islet. The numbers in parentheses give the percentage of the post-nuclear supernatant.

-unstimulated islets, we can speculate as to possible mechanisms of translational control. Although the rate of proinsulin synthesis in the glucose-stimulated islets was 10 times that in the unstimulated islets, only a small difference between the amount of proinsulin mRNA in both membrane-bound polysome fractions was observed (58% and 40% in the stimulated and unstimulated islets, respectively). These results indicate that proinsulin synthesis is mainly regulated by enhancing the translation efficiency of proinsulin mRNA on the membrane-bound polysome.

A significant amount of proinsulin mRNA was also detected in the post-polysomal supernatant fraction (Table 1). The amount of proinsulin mRNA in the supernatant fraction was decreased by glucose stimulation. This decrease in proinsulin mRNA in the supernatant fraction was closely correlated with an increase in proinsulin mRNA in the membrane-bound polysome fraction. Therefore, the regulation by glucose of proinsulin synthesis in pancreatic islets is assumed to be achieved also in part by the transfer of proinsulin mRNA in the supernatant to the membrane-bound polysome.

Recent observations indicate that the rates of synthesis in proteins such as ovalbumin[14], globin[15], immunoglobulin[16], growth hormone[17], tyrosine aminotransferase[18] and tryptophan oxygenase[19] are closely correlated with the amount of the corresponding mRNA in cells. Therefore, the expression of genes of these proteins as well as many other proteins in eukaryotic cells is believed to be regulated at the transcription level.

The translational control of proinsulin synthesis by glucose as reported here seems to be a unique regulation of protein synthesis in eukaryotic cells. As insulin regulates the glucose level in the blood, the rates of both secretion and synthesis of insulin are required to change rapidly according to the change of the blood glucose level. Translational control may be a means of ensuring rapid regulation of proinsulin synthesis by glucose.

A ρ-recognition site on phage λ *cro*-gene mRNA

Susan L. Bektesh* & John P. Richardson

Program in Molecular, Cellular and Developmental Biology, Department of Chemistry, Indiana University, Bloomington, Indiana 47405

The synthesis of RNA catalysed by RNA polymerase from *Escherichia coli* is terminated at specific sites on DNA templates through the action of a multimeric basic protein known as ρ (refs 1, 2). Three lines of evidence suggest that an interactions of ρ with the nascent RNA is important for this termination. First, ρ binds strongly to RNA[3]; second, ρ expresses an RNA-dependent ATPase activity which is essential for termination[4,5]; third, RNA polymerase does not terminate RNA synthesis at ρ-dependent sites when the nascent RNA is digested by ribonuclease during transcription[2,6]. From the fact that certain RNAs, particularly single-stranded, pyrimidine-rich polymers containing at least 10% cytidylate residues, are more effective than other RNAs at promoting ρ-ATPase, it has been proposed[7] that ρ recognises specific sites on a nascent RNA for its action. We present evidence here that ρ does bind at a specific region on a mRNA transcribed from bacteriophage λ DNA.

A precisely located site where the synthesis of an RNA molecule is terminated by ρ action is at a region, called t_{R1}, that is 92–96 base pairs to the right of the ochre translation termination triplet for the *cro*-gene sequence on λ DNA[8]. Transcripts initiated at P_R on λ and terminated in this region are 308–312-nucleotide-long RNAs and sediment at 8–9S (ref. 9). We call these, collectively, λ *cro* mRNA, and its sequence, as deduced from published information on the sequences of the λ DNA in the area of the *cro* gene and the 5′ and 3′ ends of the RNA, is given in Fig. 1.

To study the binding of ρ to a specific site on λ *cro* mRNA, the RNA is prepared by transcription *in vitro* of a λ DNA fragment containing the sequences from the restriction nuclease *Hin*dIII site at position 77.6 (in gene C_I) to the *Eco*RI site at position 81. This fragment actually codes for the synthesis of two RNAs *in vitro*, λ *cro* mRNA and λ *oop* RNA. From studies using a nitrocellulose filter binding assay, we have found that ρ forms a complex with λ *cro* mRNA, but not with λ *oop* RNA. We estimate that the association constant for the ρ–λ *cro* mRNA interaction is of the order of 10^8 M^{-1}. This binding is not high enough to isolate a fragment of RNA protected by ρ against

Fig. 1 The nucleotide sequence of λ *cro* mRNA. This sequence is based on published information[8,11–13]. Dots are placed after every 10 residues. The parenthesis at the 3′ end indicates that termination occurs at any one of those bases. The AUG initiation codon and UAA termination codon for *cro* protein synthesis at residues 19–21 and 217–219, respectively, are underlined. The overlining with arrows designates some inverted sequence repetitions that might be involved in *cro* mRNA secondary structure. The symbols ⫯ and ꝭ indicate preferred sites of cleavage with T$_1$ and pancreatic ribonucleases, respectively. The wavy underlining indicates the region where bond cleavage is inhibited by ρ.

ribonuclease digestion; however, it is high enough for ρ partially to protect sites on the RNA against cleavage by ribonucleases. We use this effect to demonstrate that ρ binds to a specific site on λ *cro* mRNA.

To simplify the task of locating cleavage sites on λ *cro* mRNA, we use RNA labelled at the 5′ end and analyse the size distribution of its partial cleavage products by polyacrylamide gel electrophoresis. With this technique, the size of a labelled RNA fragment can be directly related to the point of cleavage on the primary structure of the *cro* RNA. λ *cro* mRNA labelled at the 5′ end was prepared by transcription of the λ *cro*-gene DNA fragment *in vitro* (with ρ present) using [γ-^{32}P]ATP. As λ *oop* RNA is initiated with GTP, the only labelled product is λ *cro* mRNA, which because of the heterogeneity in its termination, produces an unresolved group of bands on the gel rather than a single sharp band (Fig. 2, lanes 1 and 8). A partial digest of this RNA with pancreatic ribonuclease produces several distinct new bands, the two most prominent of which are at positions corresponding to RNA chain lengths of 90 and 125 nucleotides (lane 2). When the cleavage is carried out in the presence of a 10-fold molar excess of ρ over the RNA, many of the bands remain unchanged (lane 3), but the intensities of the bands from position 115 to position 129 are lower. Similarly, partial digestion of free λ *cro* mRNA with T$_1$ ribonuclease produces three very distinct bands (lane 6), including one at position 127 that is totally absent when the digestion is carried out in the presence of ρ (lane 7). The inclusion of ATP in the reaction mixture has no effect on the pattern of bands formed nor on the sites protected by the presence of ρ. (Lanes 4 and 5 show the results with pancreatic ribonuclease digestion with and without ρ present, respectively; the results with T$_1$ ribonuclease are not shown.)

The results show that there is a wide range of susceptibility of the bonds in λ *cro* mRNA to attack with ribonucleases. The most abundant products found after a limited partial digestion are the result of breakage at the most susceptible bonds. The very distinct pattern of products found is a clear indication that λ *cro* mRNA has a highly ordered secondary and perhaps tertiary structure. Presumably the most susceptible bonds are at exposed portions of the RNA. The presence of ρ clearly inhibits ribonuclease action at some susceptible points but not others. As T$_1$ ribonuclease, pancreatic ribonuclease and ρ are all more active on single-stranded RNAs than on double-helical RNAs, we expect ρ to bind to an exposed portion of the RNA that would also be a preferred site for ribonuclease action. Thus, the very specific inhibition caused by ρ is probably the result of a direct blockage of a cleavage site by the bound ρ molecule, rather than the result of a conformational change at the cleavage site induced by the binding of ρ to some other sequence of the RNA.

Because there are so few sites that are highly susceptible to cleavage, this experiment gives only limited information on the extent of the λ *cro* mRNA that could be in contact with ρ. The results suggest that there is some degree of contact with the region of residues 115–128, but that contact does not extend to position 88 on one side nor position 172 on the other side. With poly(C), ρ can bind up to 60 nucleotides in a single stretch[10]. However, as the binding of ρ to λ *cro* mRNA is several orders of magnitude weaker than its binding to poly(C), the extent of contact could involve many fewer nucleotides.

Based on an examination of the primary structure of λ *cro* mRNA, we predicted that a likely site for ρ binding would be the pyrimidine-rich segment of RNA on the part of the untranslated

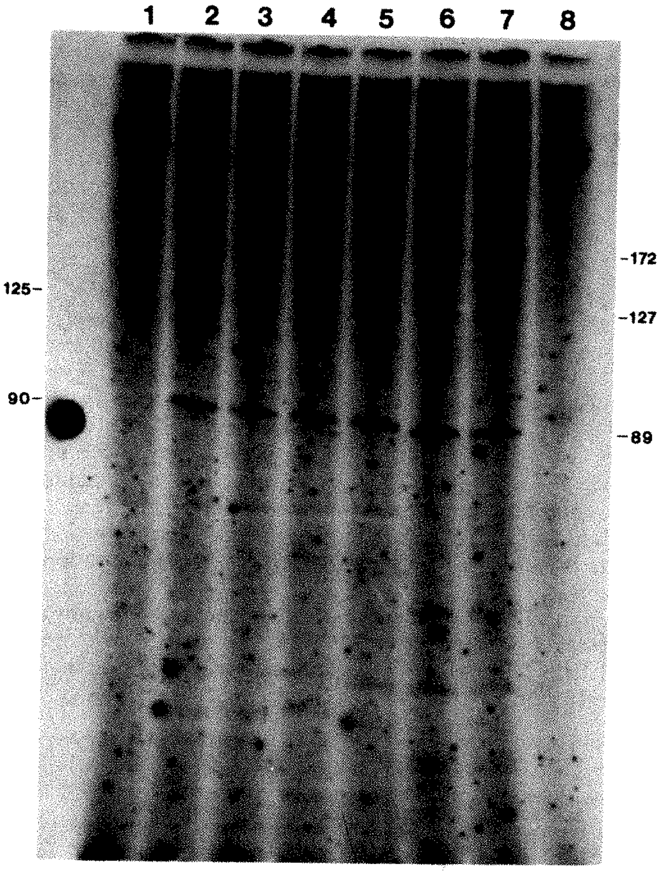

Fig. 2 Effect of ρ on the cleavage of λ *cro* mRNA with pancreatic and T$_1$ ribonucleases. [5′-^{32}P]-labelled λ *cro* mRNA was synthesised *in vitro* in a reaction mixture containing 5.6 pmol *E. coli* MRE 600 RNA polymerase holoenzyme, 5.6 pmol ρ protein, 1 pmol λ *cro* DNA fragment (77.6–81.0 map units of λ DNA), 0.1 mM each [γ-^{32}P]ATP (10–20 Ci mmol^{-1}), GTP and UTP, 0.05 mM CTP, 40 mM Tris-HCl, *p*H 8, 10 mM MgCl$_2$, 50 mM KCl, 0.1 mM dithiothreitol and 0.1 mM EDTA in a total volume of 0.1 ml. After incubation for 20 min at 37 °C, the RNA was purified by extraction successively wipenol and with a chloroform/isoamyl alcohol mixture (24 : 1) and precipitated with 2 volumes of 95% ethanol. After centrifugation for 30 min at 20,000*g*, the pelleted precipitate was washed in 0.5 ml 95% ethanol and the washed precipitate dissolved in a solution containing 10 mM Tris-HCl, *p*H 7.4, 10 mM KCl, 10 mM MgCl$_2$, 0.1 mM dithiothreitol, 0.1 mM EDTA, bovine serum albumin (50 μg ml^{-1}) and *E. coli* tRNA (1 mg ml^{-1}). The samples analysed contained, in 10 μl total volume, 0.1 pmol of [5′-^{32}P]λ *cro* mRNA (~10,000 c.p.m.). Samples with ρ contained 0.4 μg and were preincubated for 1 min at 37 °C; ATP, when present, was 1 mM. Ribonuclease treatments at 37 °C were initiated by adding 1 μl of either T$_1$ ribonuclease (Sankyo-Calbiochem, 80 units ml^{-1}) or pancreatic ribonuclease (Worthington, 5 × 10^{-3} units ml^{-1}) and were terminated after 15 min by the addition of 1 μl 1% diethyl oxydiformate. After adding 10 μl of a solution containing 40% sucrose, 0.1% xylene cyanol and 0.1% bromphenol blue, the samples were applied to a 10% acrylamide gel (14 cm × 25 cm × 0.15 cm) containing 7 M urea in 90 mM Tris, 90 mM boric acid, 4 mM EDTA and 0.1% SDS. After electrophoresis for 5 h at 350 V, the lowest section of the gel containing residual unincorporated [γ-^{32}P]ATP was cut away and the rest of the gel was washed in H$_2$O for 0.5 h (to remove urea), dried and exposed to Kodak NS-2T X-ray film in the presence of a Cronex Lightning-plus intensifying screen at −70 °C. Lanes 1 and 8, untreated RNA; lanes 2–5, RNA treated with pancreatic ribonuclease. ρ was present in samples shown in lanes 3 and 4 and ATP was present in samples shown in lanes 4 and 5. Lanes 6 and 7, RNA treated with T$_1$ ribonuclease in the absence and presence of ρ, respectively. The dark spot at the left marks the position of the xylene cyanol dye.

tail of the RNA that starts after the ochre chain termination triplet at position 220 and runs to the start of the proposed hairpin loop structure (*nut*R [see ref. 8]) at position 244. By itself, this region would probably have very little secondary structure. Although there is evidence that bonds from residues 220 and 244 are cut with pancreatic ribonuclease, the sites are not as sensitive as those at positions 90 and 125, and the single G residue at position 228 is resistant to T_1 ribonuclease action. Thus, it is likely that this stretch of RNA is protected by folding of the RNA. As ρ has no obvious effect on the activity of pancreatic ribonuclease in that region, it may be that the folding of the RNA prevents it from being an effective ρ binding site as well.

The results presented here indicate that ρ does bind to a specific site on λ *cro* mRNA and that is within the sequence coding for the *cro* protein 180 residues from the 3′ end rather than on the untranslated tail. In the current models[2,7,10], it is proposed that ρ protein functions in termination primarily to effect the release of RNA molecules from a transcription complex in which the RNA polymerase has paused at a termination site on the DNA template. As the sites for pausing are apparently determined by the interaction between the RNA polymerase, DNA and the nascent RNA[8], the initial site of attachment of the release factor need not be at a sequence adjacent to the 3′ end. Thus, the binding site detected in this study could be relevant to ρ function in termination. However, because the structure of RNA is very sensitive to the environment, which is not the same for a nascent RNA as it is for an isolated RNA, we cannot be certain that ρ binds to the same region on the nascent RNA. Hence, although we have identified for the first time a specific site for the interaction between ρ and a mRNA, further experiments will be needed to show whether this site is recognised by ρ during the process of transcription termination.

Potential of *Escherichia coli* isolated from nature to propagate cloning vectors

James P. Robeson*, Raúl M. Goldschmidt & Roy Curtiss III

Department of Microbiology, Medical Center, University of Alabama in Birmingham, Birmingham, Alabama 35294

Concern has been shown in the scientific community with regard to the potential risk that the transmission of foreign genes from *Escherichia coli* K12-cloning vector systems to other microorganisms might represent[1]. Because of this we have attempted to evaluate the frequency in nature of *E. coli* strains that can serve as recipients and/or hosts for genetic information harboured by various *E. coli* cloning vectors used in recombinant DNA research. We assumed that genetic transfer from *E. coli* K12 to other *E. coli* strains was more likely than to bacteria of other species or genera, and consequently examined natural *E. coli* isolates for traits that would reflect their ability to propagate and/or maintain cloning vectors. In particular, we were interested in assessing the role that transduction might have in the dissemination of cloned genetic information. We also wanted to determine whether naturally occurring strains could acquire and stably maintain phage λ derived cloning vectors that generally contain *amber* mutations in essential genes[2–4]. By examining natural bacterial populations we attempted to evaluate the fitness of auxotrophic mutations that are generally introduced into *E. coli* K12 hosts used in recombinant DNA experiments. Therefore, we determined among natural isolates of *E. coli* frequency of strains exhibiting: (1) sensitivity to phages P1 and λ; (2) *amber* suppressor mutations; and (3) auxotrophic mutations. The results presented here allow an estimation of the feasibility and limitations of the successful spread among *E. coli* strains in nature of recombinant DNA molecules contained in particular *E. coli* K12 hosts.

In terms of propagation of cloning vectors, we considered it important to evaluate the possiblity that they might be transferred to and among natural *E. coli* strains through generalised transduction by a phage like P1. Although P1 is known to have a wide host range[5,6], the prevalence of P1-mediated transduction in nature, and the incidence of P1 sensitivity among natural isolates of *E. coli* are not known. We studied this last parameter for an indication of the importance which P1 transduction might have on the dissemination of plasmid cloning vectors among naturally occurring bacteria. Sensitivity to P1 of the *E. coli* isolates studied was determined using the phage derivative P1CM*clr100* (ref. 7) which confers resistance to chloramphenicol (Cm) to lysogenised cells. A substantial majority of the *E. coli* strains studied (about 70%) were found to be sensitive to P1 (Table 1, *c*). Generally these strains were lysogenised by P1CM*clr100* at frequencies ranging from 10^{-2} to 10^{-4}.

In the case of λ cloning vectors an inherent safety feature seems to derive from the low incidence of sensitivity to λ found among natural isolates of *E. coli* using a plaque formation assay[4]. However, these studies may have underestimated the sensitivity to λ of those strains, as plaque formation requires successful propagation of the phage and is therefore affected by factors such as reduced adsorption, restriction and/or the presence of a homoimmune phage[8], all of which will reduce the plating efficiency of λ. Considering these limitations to using lysis as a test for λ-sensitivity, we decided to examine our *E. coli* isolates for sensitivity to phage λ using the thermoinducible derivative λ*cam105* (ref. 9) which contains in its genome the determinant for Cm resistance, Tn*9*.

By these means, penetration of λ into λ-sensitive *E. coli* cells can be detected by the acquisition of a Cm-resistant phenotype that might result from lysogenisation by λ*cam105* and/or by transposition of Tn*9* to the chromosome, or a resident plasmid, or phage of the strain being studied. About 2% of the *E. coli* strains tested yielded Cm-resistant clones when infected with λ*cam105* (Table 1, *d*). These clones were analysed further and it was found that in eight out of nine instances, the Cm-resistant derivatives could grow at 30°C but not at 42 °C. This indicated that they were lysogens of λ*cam105* since the parental strains showed unimpaired growth at 42 °C. In addition, lysates prepared from the Cm-resistant derivatives which were thermosensitive could only transduce to Cm resistance *E. coli* K12 strains that were not λ-lysogens. The frequency of lysogenisation by λ*cam105* was estimated to be between 10^{-3} and 10^{-4}. The strain that gave rise to Cm-resistant clones which were not thermoinducible might represent a case in which λ was lost after infection, and the Cm-resistant phenotype resulted from a Tn9 transposition event. We noted that the λ derivative λ*vir* (ref. 10) did not form plaques on any of the strains shown to be infectable by λ*cam105*. This indicates that a plaque assay is generally not

Table 1 Characteristics of natural isolates of *Escherichia coli*

Origin[a]	No. of isolates	Fraction of isolates sensitive to phages		Fraction of isolates with *amber* suppressor mutations[f]	Fraction of isolates containing auxotrophic mutations[i]
		P1[c] and	λ[d]		
Infections	325	212/310	2/237	2/254[g]	37/325
Stools	190	135/180	7/143	0/154	11/188
Polluted water	35	20/23	0/34	0/35	3/35
Totals	550	367/524	9/414[e]	2/443[h]	51/548
(%)		(70.0)	(2.1)	(0.4)	(9.3)

a, *E. coli* strains from infections were obtained from CDC stocks (Atlanta, Georgia) and additional strains were isolated from specimens collected at the UAB hospitals. All strains from infections were of human origin. Strains from faecal samples from both healthy and diseased human individuals were also obtained from UAB hospitals and CDC, respectively. *E. coli* strains were isolated from polluted water samples collected from wells and water systems around the Birmingham area. The strains from CDC (328 isolates) had been originally collected between 1972 and 1976. In most cases, the O, H and K antigenic types had been determined. Strains from UAB (187 isolates) and from polluted waters were collected during 1977. No serotyping was done with these strains.

b, The total number of isolates includes strains that were resistant to one or more of the following drugs: Ap, Tc, Km and Cm (Sigma). Some of these strains, depending on the resistance(s) they displayed, were not tested for *amber* suppressors and/or sensitivity to phages P1 and λ due to experimental design.

c, Lysates of P1CM*clr100* were prepared by thermoinduction of the *E. coli* K12 P1CM*clr100* lysogen χ1932 (F$^-$ *tsx* λ$^-$ *nalA rpsL*). *E. coli* strains to be tested were grown at 37 °C to a density of 1×10^8 cells ml^{-1} in L broth[13] supplemented with 2.5×10^{-3} M CaCl$_2$. Cultures were infected with P1CM*clr100* at room temperature using the phage at a multiplicity of infection of 1. After allowing 20 min of preadsorption at 30 °C, samples of the infected cultures were plated on Penassay agar (PA, Difco) supplemented with 12.5 μg ml^{-1} Cm. After 24–36 h of incubation at 30 °C, plates were examined for the presence of Cm-resistant lysogens.

d, Lysates of λcI857*cam105* were prepared by thermoinduction of its *E. coli* K12 host MGBO (F$^-$ *thi rha trkA*$_{trkD}$) (provided by L. A. MacHattie). λ*cam105* was then used to detect λ-sensitive strains using the same procedure described for P1-sensitivity screening, except that the cells were grown in L broth without glucose and supplemented with 1×10^{-2} M MgSO$_4$. Also, selective plates contained 20μg ml^{-1} Cm.

e, Strains lost on storage at 4 °C account for the lower number of isolates tested for λ-sensitivity in relation to the number examined for P1-sensitivity.

f, See text for experimental rationale. *E. coli* χ1776 (F$^-$ *tonA53 dapD8 minA1 supE42* Δ40[*gal-uvrB*] λ$^-$*minB2 rfb* – *2 nalA25 oms* – *2 thyA142 metC65 oms* – *1* Δ29[*bioH-asd*] *cycB2 cycA1 hsdR2*)[14] containing the plasmid pLM2 [Ap(am) Tc(am) Km][11] was used as donor in matings with the natural *E. coli* isolates tested. χ1776 (pLM2) and the recipient strain under examination were grown to a density of 1×10^8 cells per ml in L broth supplemented with 100 μg diaminopimelic acid (DAP) and 40 μg thymidine (Thd) per ml. Samples (0.1 ml) of donor and recipient were mixed on PA plates containing DAP and Thd and incubated overnight at 37 °C. Generally, the recipient strain was heat shocked before mating to minimize restriction of the incoming plasmid[15]. After incubation, the mating mixture was resuspended in BSG[16] and samples were plated onto PA containing 100 μg ml^{-1} Km to select pLM2 transconjugants. Selection against the donor was achieved by omitting DAP and Thd in the PA Km plates. A minimum of 5 pLM2 transconjugants of each natural *E. coli* strain tested were examined for their ability to grow in the presence of Ap (25 μg ml^{-1}) and/or Tc (25 μg ml^{-1}) to determine if the *E. coli* strain being studied contained an *amber* suppressor function.

g, The two strains showing *amber* suppressors were of human origin and had been originally recovered from infectious episodes of the urinary tract and blood. The strains were stocked at CDC with the numbers 3764–73 (urine isolate) and 3885–74 (blood isolate). Their serotypes were O undetermined: H4 and O16: H6, respectively. Both were prototrophs, P1-sensitive and λ-resistant. Both strains constituted homogeneous *amber* suppressor populations.

h, No. of strains into which pLM2 was successfully transferred to test for *amber* suppressors. The actual number of isolates that could have been tested for suppressors was 486 out of the 550 originally collected.

i, The auxotrophic character of the strains examined was determined by their inability to grow on minimal agar[16] plates with 1% glucose as carbon source.

sensitive enough to determine whether a particular *E. coli* strain can be infected by λ or not.

It was mentioned above that phage λ-derived cloning vectors generally possess *amber* mutations in essential genes[2–4]. It has also been proposed (but not yet accomplished) to construct non-conjugative plasmid cloning vectors with the same type of mutations. The purpose of constructing vectors with *amber* mutations is to confine their full expression to an *E. coli* K12 host with an *amber* suppressor. This approach to the development of safer vectors for cloning was obviously based on the assumption that the majority of bacterial strains found in natural environments would not contain *amber* suppressors and thus would not propagate cloning vectors should they accidentally acquire them. However, no data are available on the incidence of natural bacterial strains possessing *amber* suppressor mutations. We sought to detect such mutations among the *E. coli* isolates collected using the plasmid pLM2 (ref. 11). This plasmid is a derivative of RP1, a broad host range plasmid that specifies resistance to ampicillin (Ap), tetracycline (Tc) and kanamycin (Km). pLM2 differs from RP1 in that the Ap and Tc markers have *amber* mutations. Consequently, these antibiotic resistances are expressed only in a host strain that contains an *amber* suppressor. Therefore, pLM2 was used to detect *amber* suppressors by transferring it to the test strains and verifying whether resistance to Ap and Tc was expressed. We could transfer pLM2 to 91% of the strains that were suitable to be tested for *amber* suppressors (Table 1, *f*, *h*). Only two *E. coli* strains (representing about 0.4% of the total examined) were found containing *amber* suppressors. Both suppressor strains were detected among a group of isolates obtained from the Center for Disease Control (CDC), Atlanta, Georgia (see Table 1 *g*, for additional information).

Generally, *E. coli* K12 derivatives used as hosts in recombinant DNA experiments have specific auxotrophic mutations that result in a decrease in viability of the strains when they are placed in laboratory conditions that mimic a natural environment. Examples of mutations that severely hinder survival of *E. coli* K12 derivatives are those that lead to the requirement of cell wall components like diaminopimelic acid and/or precursors of nucleic acids like thymidine. An independent way of assessing the effect of such mutations on the survival of a particular natural strain is to determine whether the corresponding phenotypes are present among natural bacterial isolates. Therefore, we tested our *E. coli* isolates for the presence of auxotrophic mutations and whenever possible the nature of the metabolic requirement was determined. We found that approximately 9% of the natural *E. coli* strains studied were auxotrophs (Table 1), a result that is in agreement with available information[12]. When further analysed for the nature of their nutritional requirement, 77% of the auxotrophic strains were found to require niacin. The rest required either a different vitamin (thiamine, pantothenate) or certain amino acids, namely cysteine or methionine. No purine or pyrimidine requirers were found. We noted that a group of *E. coli* isolates from urinary tract infections showed the highest incidence (25%) of auxotrophic strains.

The results of this investigation suggest that P1-mediated transduction might be an important mechanism for dissemination of genetic information in nature in view of the high incidence of P1-sensitive strains found among the *E. coli* isolates that were examined. This observation is consistent with the broad host range of P1 (refs 5, 6). However, additional experiments are necessary to evaluate further the possible role of P1 in the transmission of genetic material between natural bacterial populations. It would be desirable to determine titres of P1-like phage in nature, either as a free phage or as a prophage in lysogenic cells; in addition, stability and infectivity data of P1-like phage particles in natural conditions would be required. This information would be important in view of results that show that P1 is able to transduce plasmids similar to those used as cloning vectors, although at a lower frequency than for chromosomal genes (R. Goldschmidt and M. Inoue, unpublished).

In terms of λ cloning vectors, our observations indicate that these cloning vehicles have inherent safety features that derive from the relatively low incidence of λ-sensitive strains among naturally occurring strains of *E. coli*. From the results that indicate the presence at low frequency of *amber* suppressor mutations among the *E. coli* isolates examined, it is apparent that cloning vectors with *amber* mutations in essential genes contained in bacterial hosts with suppressors, offer a safety advantage over vectors lacking *amber* mutations. We estimate that the probability of successful expression of an *amber*-containing cloning vehicle would be reduced at least 100-fold when compared to that of a vector without such genetic lesions in its genome.

The fact that we were able to detect auxotrophs among the bacterial strains tested suggests that certain vitamin and amino acid requirements do not necessarily represent a selective disadvantage to the bacteria that possess them. On the other hand, the diversity of auxotrophic mutations was rather limited and it seems unlikely that all possible types of auxotrophs will be found among natural bacterial isolates. In particular and as expected, we did not find any of the phenotypes associated with mutations that result in a severe impairment of the ability of *E. coli* K12 derivatives to survive in natural environments.

We thank Drs Don J. Brenner and W. James Alexander for providing most of the strains used, Dr Josephine Clark-Curtiss for preparing the derivative of χ1776 containing pLM2 and Ms Denise Sweat for assistance in determining antibiotic sensitivity patterns. The Graduate School of the University of Alabama in Birmingham provided partial support.

Anisotropy of Young's modulus of bone

J. Lawrence Katz*

Department of Orthopaedic Surgery, Harvard Medical School and The Children's Hospital Medical Center, Boston, Massachusetts 02115

Bonfield and Grynpas[1] have compared their experimental data for Young's modulus of elasticity versus the angle of orientation of the specimen to the long axis of bone with a theoretical curve predicted from a calculation for fibre reinforced materials proposed by Currey[2]. As a result of the poor agreement between the two curves they conclude "... an alternative model is required to account for the dependence of Young's modulus on orientation" (ref. 1). Such an alternative has been under development in my laboratory for the past 8 years (refs 3–7). It is a two-level hierarchical fibre-reinforced composite model which appears to provide a much more suitable description of the behaviour of bone as a fibre-reinforced composite material.

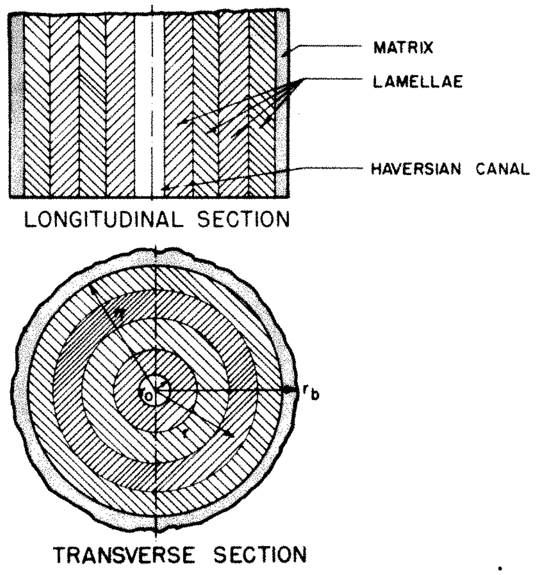

Fig. 1 A single osteon modelled as a hollow fibre for the Hashin–Rosen[9] calculation. r_0 is the radius of the haversian canal (hollow), r_f is the radius of the single osteon (fibre) and r_b is the radius of the osteon plus cement line (fibre and matrix).

At the first level of the model, a single osteon is treated as a coherent entity, modelled as a hollow, right circular cylinder comprised of concentric lamellae surrounding the haversian canal (Fig. 1). On the second level the osteons or interstitial lamellae are assumed to be packed in a pseudo-hexagonal arrangement (Fig. 2), as suggested for compact cortical bone by Yoon and Katz[8] based on microscopic observations and ultrasonic wave propagation measurements.

The Hashin–Rosen calculation[9] for hexagonally and randomly (nearly hexagonally) arrayed hollow fibre-reinforced composites can now be applied directly. In this model only five independent effective elastic constants are required to characterise completely the anisotropic elastic properties of the material, either exactly as in the case of hexagonal arrays or approximately for random (nearly hexagonal) arrays. Variational techniques provide a set of bounds for the five effective

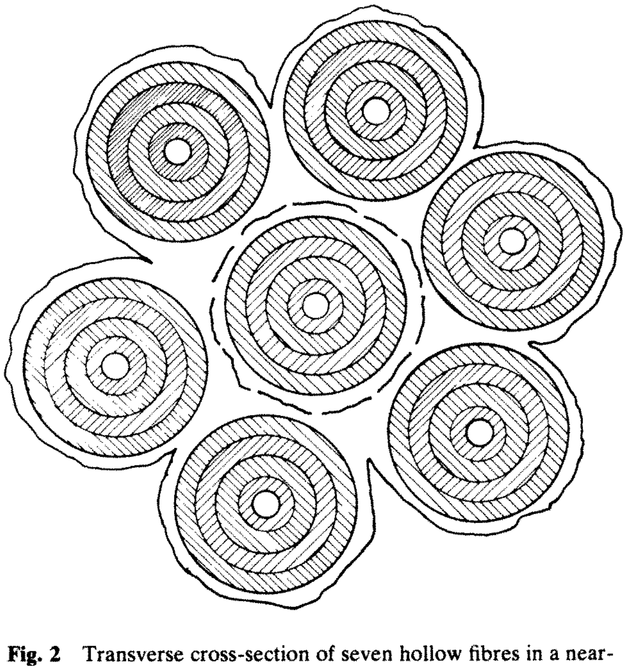

Fig. 2 Transverse cross-section of seven hollow fibres in a near-hexagonal array modelling a specimen of cortical haversian bone. (The number of lamellae depicted for each osteon is for artistic purposes only and does not affect the calculation.)

0028–0836/80/010106—02$01.00

elastic constants; the upper bounds are obtained by using displacement criteria, the lower bounds by using the stress-vector criteria.

Two kinds of input are required for this calculation. First, geometric factors are needed that include the ration of the transverse area of the haversian canal to that of the osteon, given by r_0^2/r_t^2 (Fig. 1) and denoted by V_0, and the ratio of the transverse area of the osteon to osteon plus matrix, given by r_t^2/r_b^2 (Fig. 1) and denoted by V_t. Second, mechanical properties are needed that include the Young's modulus and Poisson's ratio for both the fibre represented here by the single osteon (E_{OST} and ν_{OST} respectively) and the matrix represented here by the ground substance (E_{GS} and ν_{GS} respectively). Reported values of E_{OST} under various ultrastructural configurations[4] agree well with values for single osteons measured by Frasca[10]; values of ν_{OST} have also been derived from his data. Values for the ground substance have been inferred from the angular dependent properties of bone obtained from ultrasonic experiments[8].

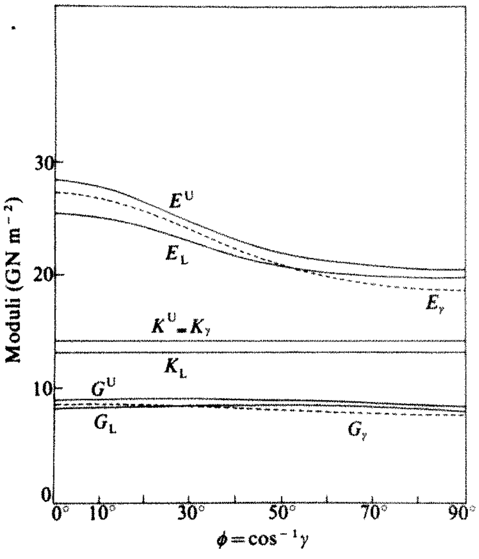

Fig. 3 The angular dependent variation of the elastic moduli for human cortical bone with respect to the orientation of the long axis of the bone (ϕ) calculated from the ultrasonic data of Yoon and Katz[8] (Young's modulus, E_γ; bulk modulus, K_γ; and shear modulus, G_γ, are denoted by - - -) compared with the theoretical curves representing the upper and lower bounds on the angular dependent behaviour of the elastic moduli using the Hashin–Rosen calculation[9]. (Young's moduli, E^U, E_L; bulk moduli, K^U, K_L; and shear moduli, G^U, G_L respectively are denoted by ——.) Input parameters are: $E_{OST} = 40.0$ GNm^{-2}; $E_{GS} = 10.0$ GN m^{-2}; $\nu_{OST} = 0.30$; $\nu_{GS} = 0.25$; $V_0 = 0.10$ and $V_T = 0.70$.

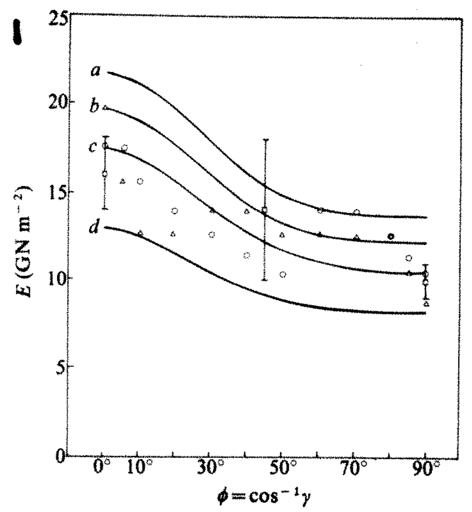

Fig. 4 The variation of Young's modulus for bovine femoral specimens with respect to the orientation of specimen axes cut at the angle ϕ to the long axis of the bone for wet (○) and dry (△) conditions from the work of Bonfield and Grynpas[1] compared with the angular dependent behaviour of Young's modulus (——) computed using the Hashin–Rosen calculation[9]. Each curve represents a different lamellar configuration of collagen fibres and hydroxyapatite crystallites within a single osteon. *a*, 65% longitudinal fibres; *b*, 57% longitudinal fibres; *c*, 50% longitudinal fibres; *d*, 37%% longitudinal fibres. Other input parameters are: $E_{GS} = 5.5$ GN m^{-2}; $V_0 = 0.20$; and $V_T = 0.80$.

These ultrasonic measurements have yielded five independent elastic stiffness constants which also can be used to calculate the technical moduli as a function of the angular orientation with respect to the stress axis. The angular dependence of the Young's E, bulk, K, and shear, G, moduli calculated from the ultrasonic data are compared on Fig. 3, with a set of upper and lower bound curves generated by using the best pair of five effective elastic constants obtained from a large number of sets computed using the Hashin–Rosen formalism[9]. The values of these ultrasonic moduli for dry bone are all greater than those obtained by mechanical testing or low frequency sound measurements on wet bone (Fig. 4). This is due partly to the fact that dry bone is stiffer and more rigid than the same sample of bone when wet, and partly to the strain rate dependent behaviour of bone which results in increased stiffness with increase in strain rate[11]. Several groups of such curves have been analysed in detail to obtain representative sets of values for both the Young's modulus and Poisson's ratio of the matrix based on scaling the ultrasonic data to the mechanical and low frequency sound measurements.

Various combinations of these parameters have been used in calculations, based on the Hashin–Rosen formalism, which then generate sets of the five effective elastic constants. These constants are then used to calculate the angular dependence of such technical moduli as the Young's and shear moduli as a function of angular orientation with respect to the stress axis. These calculations have been used as the basis for determining which sets of parameters were used in generating curves *a–d* (Fig. 4) in order to model the data of Bonfield and Grynpas. Additional confirmation of this type of angular dependent behaviour for the elastic properties of bovine bone is shown in Fig. 4. The values measured for bovine bone specimens cut at 0°, 45° and 90° to the bone axis (denoted by the open squares with error bars) are from ref. 12.

Although this model simulates the behaviour of bone quite closely it cannot provide an exact description. It handles only one size of osteon in a given calculation. However, it can be adjusted to yield an average behaviour or to predict the upper and lower bounds on the elastic behaviour by the choice of lamellar micro- and ultrastructure (number of lamella, size of the haversian canal, fibre orientations and so on) as is shown in part by Fig. 4.

MATTERS ARISING

Rotating lunar globules

SEVERAL theories have been proposed for the origin of the shapes of lunar dumbbell and ellipsoidal glass globules. The rotational theory[1] assumes that they solidify while rotating in free fall above the lunar surface, the rotation giving the elongation in form. A second theory imagines solidification of a jet of liquid again above the lunar surface and at some time during the break-up of the jet[2-4]. More recently Chernyak and Nussinov[5] have proposed that the shapes are caused by the sudden freezing of a vibrating droplet. They also cite arguments against a rotational origin. However, there is now much evidence favouring the rotational hypothesis.

Chernyak and Nussinov propose that "the drops vibrate" and "because of the exponential dependence of viscosity on temperature the particle solidifies and memorises its shape". Such a proposal is completely untenable as a glass drop cannot pass from an essentially liquid to solid state in a time that is short compared with its vibrational period. The period of vibration of a droplet of diameter 100 μm is about 10^{-4} s. Even assuming it radiates as a perfect black body the drop in temperature of such a globule during its vibrational period is between 0.1 and 0.01 K. Although the viscosity of glasses varies very rapidly with temperature (three orders of magnitude for a temperature change of 100 K) it is impossible that there can be any appreciable change in viscosity during a single period of oscillation, let alone during the small fraction of the period required by the vibrational hypothesis. Similar numerical analyses for larger or small droplets yield essentially the same conclusion because the ratio of the vibrational period to the time taken to cool through a given temperature interval varies only slowly with particle size[1] (in fact, as the square root of its linear dimensions).

Arguments by Chernyak and Nussinov[5] against the rotation hypothesis depend on the instability of dumbbell shapes and the effect of Coriolis forces which would bring about S or crescent shaped particles. Although several curved smooth glassy particles have been found in lunar soil and it is reasonable to use a Coriolis force mechanism to explain their shape, if the initial temperature of a particle is sufficiently high, the cooling time is long enough for viscous forces to damp out all appreciable internal motion. While still liquid the globule will thus eventually rotate as a rigid body[1] and Coriolis forces are then not involved.

Chernyak and Nussinov's argument that dumbbell shapes are unstable is also not substantial. Imagine a small liquid sphere in an inertial frame held together only by surface tension forces. Suppose a small external couple acting for a limited time causes the globule to be brought into rotation. After the couple has been removed the globule will attain an aspherical rotating form in which any internal motions will gradually be eliminated by viscous damping. The form of the globule is then stable yet not spherical. The process may be repeated so that more and more angular momentum will be slowly given to the globule. Eventually the system will disintegrate but it is unclear whether before this disintegration occurs stable forms may exist with re-entrant shaped cross-sections—dumbbells.

There are many other reasons for preferring the rotational hypothesis. (1) The photographed shapes of lunar dumbbells[6] are not the same as those formed by jet break-up[7]. The latter have low curvature at their extremities. (2) The curvature of the surfaces of lunar dumbbells has been shown to agree well with that predicted from rotational theory[6]. (3) The break-up of a jet is a transitory phenomenon: a rotating dumbbell is a stable form so that the latter would be expected to occur more frequently. (4) There is no evidence that regular cylindrical liquid jets can be formed by volcanic activity or hypervelocity impacts. Such a jet is required by the jet break-up hypothesis[2,3]. Some evidence does exist for jet formation following meteorite impact[8] but here 'jet' simply implies a group of particles moving with high speed in approximately the same direction. The confusion is semantic. (5) The angular momentum of dumbbells and prolate globules is well accounted for by local inhomogeneities in surface rock at the impact site. (6) Voids both in the dumbbells and the oblate spheroids tend to be found close to the rotational axis, whereas darker and more dense particles are found closer to the extremities[9]. Generally more migration has occurred in the case of the larger particles and voids; and this is precisely what would be expected from Stokes' law and the rotational hypothesis. (7) The densities of the dumbbell extremities are found to be higher than the central portions, a result predicted by the rotational hypothesis (T. Gold, personal communication).

The rotation hypothesis supplies a means of determining the maximum temperature of droplets during their formation. It also favours a lava fountain origin for many of the green and orange lunar droplets as no dumbbell-shaped globules have been reported among these samples[10]. It is also relevant to the question raised by Butler[11] concerning whether these droplets were splashed from molten lava by impact.

Dihydroergocryptine binding and α-adrenoreceptors in smooth muscle

THE recent letter by Kunos *et al.*[1] in which they "dissociate phentolamine-suppressible ^{3}H-dihydroergocryptine (^{3}H-DHEC) binding and α-receptors" in rabbit myometrium disagrees with previous reports[2,3] and contains several puzzling features.

First, the authors assume that the concentrations of phenoxybenzamine (POB) inhibiting noradrenaline-stimulated contractility should coincide with concentrations of POB that compete for ^{3}H-DHEC binding sites. As the number of steps between receptor binding and contractility is unknown, one ought not necessarily expect such different experimental approaches to yield similar results[4,5]. Moreover, it is probably unreasonable to ascribe the effects of a partially irreversible α-adrenergic blocker (POB) on contractility solely to blockade of α-adrenergic receptors, because POB also inhibits response to serotonin, histamine and acetylcholine[6]. Second, the authors suggest that two classes of ^{3}H-DHEC binding site (K_d values 1.5 and 5.5 nM) exist in their preparations. The data used to determine those K_d values were apparently obtained from pooled determinations of different uterine preparations. In view of the likely heterogeneity between particulates of crude myometrial homogenates subjected to

0028-0836/80/010108—03$01.00

five to seven centrifugations (Fig. 1 legend[1]), selective pooling of such results is an unreasonable approach for determining two classes of site with such similar K_d values.

Third, we find that the concentration curve of ^{3}H-DHEC binding for 'control' values plotted by Scatchard analysis of these data yields a single class of ^{3}H-DHEC site ($K_d = 4.6$ nM, $B_{max} =$ 85.9 fmol per mg, $r = 0.93$). Even if the authors were correct in defining two classes of site, we calculate that in experiments carried out at 2 nM, their "high affinity sites" contribute 55% and the "low affinity sites" 45%, and in studies at 8 nM, the high and low affinity sites contribute 35% and 65%, respectively. We have constructed theoretical binding curves for two-non-cooperative sites with values for K_d and B_{max} described by the authors and find no break such as shown by Kunos *et al.* Although positive cooperativity at the low affinity class of sites might generate such a break, we have never seen such positive cooperativity in over 50 ^{3}H-DHEC binding studies with rabbit myometrium preparations.

Moreover, as binding at "high" (>5 nM ^{3}H-DHEC) concentrations is the sum of high and low affinity binding sites, the reported inhibition of ^{3}H-DHEC binding by POB only at concentrations below 4 nM ^{3}H-DHEC cannot be readily explained. Finally, our previous paper was misquoted. Attention to the reported data would indicate that oestrogen increased ^{3}H-DHEC binding at all concentrations from 0.5 to 100 nM ^{3}H-DHEC[3].

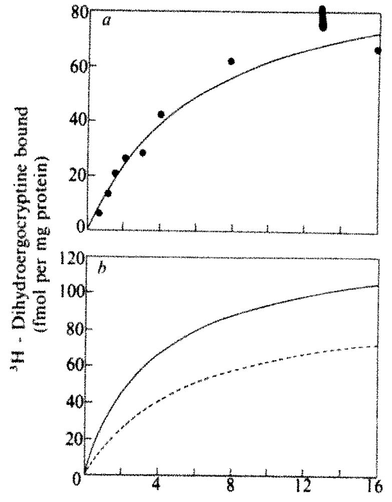

Fig. 1 *a*, Computer modelling of the control binding curve from Kunos *et al.* (Fig. 2, ref. 1). The solid circles represent graphical estimates of the binding data obtained by computerised digitisation of the published figure. The solid line is the best fit to a model for one class of binding sites according to the mass action law. The data could not be succesfully fitted to a two-site model. K_d = dissociation constant of receptors for ^{3}H-DHE = 6.2 ± 1.4 nM, R = receptor concentration = 101 ± 14 fmol per mg. *b*, Computer simulation of a control (solid line) and a POB-treatment (dashed line) binding curve, based on parameter estimates provided by Kunos *et al.*[1,2]; two classes of binding site (K_d = 1.5 nM and 5.5 nM, R = 37 and 97 fmol per mg protein) for the control curve and one class of binding site (K_d = 5.5 nM and 97 fmol per mg protein) for the POB-treatment curve (compare with Fig. 2, ref. 1).

THE report by Kunos *et al.*[1,2] on the characteristics of tritiated dihydroergocryptine (^{3}H-DHE) binding to rabbit uterine α-adrenergic receptors suggested that (1) DHE binds with differential affinity to two classes of α-adrenergic binding sites (K_d values of 1.5 and 5.5 nM, respectively); (2) phenoxybenzamine (POB), at a concentration which completely blocks the contractile response to the α-agonist noradrenaline, also selectively blocks the higher affinity class of α-adrenergic binding sites (those presumably labelled at DHE concentrations ≤3 nM) while having no effect on the lower affinity sites (those presumably labelled at DHE concentrations >3 nM).

The first conclusion which is seemingly at variance with published reports from several laboratories[3,4,5], is based on the observation of a break in the hand-drawn curve of a binding isotherm for ^{3}H-DHE (Fig. 2, ref. 1). We obtained graphical estimates of their binding data and subjected them to computer modelling, using well established methods[6–9]. Figure 1*a* (compare with Fig. 2, ref. 1) shows that their data were best fitted with a model for one class of DHE binding sites ($K_d = 6.2 \pm$ 1.4 nM, $R = 101 \pm 14$ fmol per mg protein). Attempts to fit the experimental data with a model for two classes of DHE binding sites were unsuccessful in providing parameter estimates, indicating that the data did not support the hypothesis of more than one class of DHE binding site. Computer modelling of the first five points (DHE ≤3 nM) of their binding isotherm provided similar parameter estimates for one class of DHE binding site although much less accurately ($K_d = 6 \pm 6$ nM, $R =$ 90 ± 60 fmol per mg), again in contrast with the results of their subjective graphical analysis of these early points. In agreement with the findings of other investigators[3–5] and in conflict with their own interpretation, the data of Kunos *et al.* actually indicate the presence of a single homogeneous population of DHE binding sites in rabbit uterine membranes.

Despite the inability of their experimental data to support objectively the hypothesis of two classes of DHE binding site, the parameter estimates reported by Kunos *et al.*[1,2] for these two putative classes of DHE binding site could be used to provide computer simulations (Fig. 1*b*) of control and POB-treatment curves. Such simulations should reproduce the salient features of the data as interpreted by Kunos *et al.*—the presence of a break in the binding isotherms and a difference in the control and POB-treatment curves only at low DHE concentrations (DHE ≤ 3 nM). In contrast to the hand-drawn binding curves, the simulations revealed no break. The predicted POB-treatment curve was also noticeably lower than the control curve at all concentrations of DHE, as expected after blocking of the high affinity class of binding sites, again in contrast with their experimental data.

Their second conclusion also contrasts with previously published findings[4] which indicated that POB treatment only reduced the binding capacity of the uterine α-adrenergic receptors, leaving unchanged their uniform affinity for DHE. It has been established by several laboratories that at least two distinct types of α-adrenergic receptor, termed α_1 and α_2, can be identified in radioligand binding studies[9–12] and physiological studies[13]. DHE has been found to bind with indistinguishable affinity to both subtypes of receptor[3,4,9,10]. By contrast, phenoxybenzamine has been shown in some physiological studies to be α_1 selective[13]. Thus, the observation by Kunos *et al.*[1,2] of complete blocking of the α-agonist response in the face of partial loss of DHE binding (Fig. 1, ref. 1) may be interpreted as the result of selective blockade of the α_1 subtype of DHE binding site. However, this conclusion cannot be substantiated by the DHE binding data that they provided (Fig. 2, ref. 1) and would require more quantitative binding studies involving α_1- and α_2-selective ligands such as prazosin and yohimbine, as presented elsewhere[9].

In conclusion, inappropriate and erroneous interpretation of binding data have led Kunos *et al.*[1,2] to incorrect interpretations concerning DHE binding to uterine membrane preparations. In addition, the effect of POB treatment on DHE binding at higher ligand concentrations (8 nM) reported in Figs 1 and 2 (ref. 1) are internally inconsistent. All available data (including those of Kunos *et al.*) indicate that DHE binds to uterine α-adrenergic receptors all of which show indistinguishable affinity for DHE.

This work was supported by NIH grants HL16037 and HL20339, and by a grant in aid from the American Heart Association. A.D.L. is a recipient of a 'Centennial' Fellowhip from the MRC of Canada.

KUNOS *ET AL.* REPLY—In answer to the points raised by Roberts *et al.*, the definition of receptors involves a physiological function: our findings[1] dissociate the phentolamine-suppressible binding of high concentrations of dihydroergocryptine (DHEC) from α-receptors mediating smooth muscle contraction. The low potency of phenoxybenzamine (POB) in suppressing DHEC binding was evident in earlier studies[2]; our findings confirmed and explained this discrepancy. As for the specific points raised: To their first point, yes, we should assume that, in the demonstrated absence of 'spare' α-receptors in our system[1], the potency of POB should be the same for block and for suppression of binding. Efficiency of coupling does not affect antagonists unless they act at a stage subsequent to receptors. It is also erroneous to suggest that block of responses to noradrenaline involves non-adrenergic receptors. Even if low concentrations of POB interacted with other receptors, this would be irrelevant to its effect on DHEC binding; even so, we found that serotonin and pilocarpine have no mechanical effects in rabbit uterine strips, and contractions by histamine are unaffected by 3×10^{-8}M POB, which blocks noradrenaline completely.

Concerning their second and third points, K_d values were determined in individual preparations but, due to the limited amount of membrane material, data points were concentrated either below or above 3 nM. If POB treatment is omitted, more control points can be obtained. Recently, we confirmed a small break in the DHEC binding isotherm constructed from 18 data points at close concentration intervals. Scatchard plots of such curves are linear points below 3 nM and curvilinear with initial upward convexity above 3 nM; this is very similar to recent findings in the rat heart[3]. In this latter study, positive cooperativity between sites of the second binding component has been proposed to account for the curvilinear Scatchard plot. In the absence of sufficient numbers of closely spaced data points in the area of the break (2–4 nM) such deviations are difficult to identify, particularly if the linear sections of the plot have similar slopes. Also, we found that because DHEC is adsorbed to glass and many plastic materials, total ligand concentrations must be verified in aliquots of every assay tube to avoid errors in calculating bound/free values. In answer to the fourth point of Roberts *et al.*, the reason that an expected small suppression by POB at higher DHEC concentrations was not detected is not clear. It certainly could not be explained by reversal of the block by POB. The irreversible nature of the block of α-receptor responses by POB is generally accepted[4] and this was also shown for block of ^{3}H-DHEC binding to uterine membranes in conditions identical to those used by us[5]. Direct evidence for the irreversible binding of POB to α-receptors was recently provided in studies using ^{3}H-POB of high specific activity in intact liver cells[6] or liver membranes of rats[7]. It is possible that the expected 20–30% suppression of binding may have been obscured by the relatively large variation of values at higher DHEC concentrations (Fig. 2, ref. 1). In a different set of experiments, shown in Fig. 1, ref, 1, the same POB concentration (3×10^{-8} M) suppressed the binding of 8 nM ^{3}H-DHEC by 27%. Finally, the ligand concentrations are not easily identifiable from the Scatchard plots shown[8]: in oestrogen-treated preparations there seem to be no more than three points or less than one point per preparation under 3 nM ^{3}H-DHEC.

The points raised by De Lean and Lefkowitz are the same as the third and fourth points of Roberts *et al.*, but they are also illustrated by computer analysis of our data. The inability of the computer to detect a break in our control binding curve is not unexpected; the k_d values for the two binding components were very close[1] and as the K_d of the second binding component was determined from points outside the area of the break (see Fig. 2 legend[1]), possible localised changes in binding affinity would not be reflected in the value obtained (see above). It is clear that on the basis of these data alone we should have disregarded the small break in our control curve, which is similar to the break evident in the DHEC binding isotherm reported by Williams *et al.* (Fig. 2, ref. 2). However, we could not have disregarded the major difference in the ability of POB to block DHEC binding below and above the same concentration where the break in the control curve is apparent (Fig. 2, ref. 1). Such a differential effect of a suppressing ligand is only possible if the POB-sensitive and POB-insensitive sites have different DHEC binding properties. Failure of the computer to simulate our sigmoidal POB curve indicates that DHEC binding in the real tissue is more complex than the model on which the computer program is based. For example, positive cooperativity between sites of the second binding component is a possibility compatible with all our findings (see above), although a detailed analysis of the second binding component at different levels of receptor occupancy[3] was not possible due to the limited number of data points.

In agreement with our findings and in contrast to the above conclusions of De Lean and Lefkowitz, evidence in two recent studies also indicates binding of DHEC to two sites with differential affinity. In the rat heart ARC 239, an α-receptor antagonist similar to POB in its postsynaptic selectivity[3] was also similar to POB in preferentially suppressing the binding of low concentrations of ^{3}H-DHEC[3]. In the rat liver, dissociation of 20 nM ^{3}H-DHEC had two components, indicating two binding sites with different affinities[9].

Thus, our results[1] indicate the presence in the uterus of two DHEC binding sites, only one of which, preferentially labelled at concentrations <3 nM, is involved in α-receptor mediated smooth muscle contraction. The exact nature of binding of DHEC to the second class of binding sites and the physiological function of these sites in the uterus remain to be clarified. Computer analysis of binding isotherms will give rise to erroneous conclusions unless the validity of the model used is firmly established.

Sensitivity of human bone marrow cells to cyclosporin A

FROM observations of the effect of cyclosporin A *in vitro* on committed progenitor cells of the myeloid and erythroid series (CFU-C and BFU-E), Gordon and Singer[1] have inferred that cyclosporin A has non-myelotoxic immunosuppressive activity. We find this a disturbing conclusion because although similar studies in this laboratory[2] using the semi-solid agar CFU-C assay[3] showed almost identical dose-related inhibition of CFU-C, our results also suggested that sensitivity to cyclosporin A is related to the level of differentiation of progenitors in the granulocyte–monocyte pathway, the more primitive progenitors being more sensitive. This is important because the pluripotent haematopoietic stem cell (CFU-S) from which CFU-C are derived and on which haematopoietic recovery in marrow transplantation depends, may be more sensitive to cyclosporin A than results of CFU-C assays indicate.

There is now considerable evidence that clone size potential decreases and sensitivity to factors with colony-stimulating activity (CSA) increases as progenitor cells differentiate down the granulocyte–monocyte pathway[4,5].

Our experiments showed that: (1) cells forming small clones were less sensitive to cyclosporin A than cells forming large clones; (2) cells requiring the highest levels of CSA for clone formation (that is, the most primitive progenitors) were more sensitive than cells forming clones at lower CSA levels.

Both observations point to a trend of increasing sensitivity to cyclosporin A as the CFU-C/CFU-S transition is approached and thus to the possibility of considerable myelotoxicity in conditions where CFU-S are rapidly proliferating. Even without speculating on the sensitivity of CFU-S, our results for CFU-C detected at the highest CSA levels (approximately 50, 70 and 90% inhibition at 1, 5 and 10 μg ml^{-1} of cyclosporin A, respectively) are disturbing, as 5–10 μg ml^{-1} was required for near-maximal inhibition of the most sensitive T-lymphocyte colony-forming cell population in two of three patients studied by Gordon and Singer[1].

GORDON AND SINGER REPLY—The point that cyclosporin A may be considered to have some myelotoxicity *in vitro* is well taken. In terms of bone marrow engraftment, however, myelotoxicity has not been a problem. Cyclosporin A increases the survival of rabbits grafted with allogeneic marrow[1] and is an effective prophylaxis against graft-versus-host disease in man[2,3].

Francis and Berney have suggested that pluripotential stem cells (CFU-S) may be more sensitive to the compound than committed progenitor cells (CFU-G) and that cyclosporin A may have greater toxicity towards rapidly proliferating cells. These suggestions are based on the findings that small clones, grown in agar culture, are less sensitive to cyclosporin A than large clones and that sensitivity to the compound increases with the amount of colony-stimulating activity (CSA) presented to the treated cells.

Our data[4] do not show whether cycling and non-cycling haematopoietic progenitor cells differ in their sensitivities to cyclosporin A as the study used normal steady-state cells. This aspect is certainly of interest and experimental evidence can be obtained by studying the effects of cyclosporin A on patients' colony-forming cells following bone marrow transplantation.

The design of the experiments[5] said to show an effect of CSA activity on cell sensitivity to cyclosporin A involves a preincubation step before the cells are washed and plated in agar. It seems reasonable to suggest that the apparent effect of CSA activity on cell sensitivity may result from an altered responsiveness of the cyclosporin A-treated cells to CSA (or to inhibitors). Again, this can be tested by producing full dose–response curves of post-cyclosporin A cells, preferably to a cell-free source of CSA, which will give more reliable results than cellular feeder layers.

Correlation between heart attacks and magnetic activity—a retraction

WE recently showed a significant correlation between the daily sums of Kp, the planetary index of geomagnetic activity, and the daily admissions of cardiac emergency cases to the two main hospitals in Hyderabad and Secunderabad[1]. Richard Peto of the Radcliffe Infirmary, Oxford, has re-examined our data, and finds that their distribution about the regression line is grossly sub-poissonian. This means that the correlation is higher than would be expected even if magnetic activity were the sole cause of heart attacks, and casts serious doubt on the authenticity of the data. The magnetic activity data are those published by the International Association of Geomagnetism and Aeronomy, and are above suspicion. The medical data are those used by Srivastava, Bhaskara Rao and Saxena[2] and were abstracted by colleagues of Srivastava (Bhaskara Rao, Saxena and two others) from individual case sheets and the hospital records. Srivastava and Saxena have re-examined the hospital records, which are now in a more accessible form, and are unable to reproduce the numbers abstracted earlier. We conclude that the medical data used in the two studies[1,2] are spurious, and any results derived from them should be disregarded. This may explain why Knox *et al.* have carried out a similar enquiry and failed to confirm our claims[3].

We are grateful to Dr Peto for drawing our attention to this matter, and apologise for publishing a misleading result.

Glaciation due to continental drift

COGLEY[1] has suggested that a special distribution of land is needed during glacial periods. He proposes that the onset of glaciation occurs when land masses congregate in the tropics. The average global temperature decreases as the polar regions become "slightly warmer while

0028-0836/80/010111—02$01.00

the tropics cool substantially". This is a consequence of the albedo contrast between land and water varying with latitude.

The physical situation is more complicated than Cogley suggests and it is possible that many mechanisms operate which can induce glaciation. Tarling reported an analysis of ice ages which suggested that a continental block is needed in polar areas[2], especially in the Southern Hemisphere. Nevertheless, a near-polar position is insufficient to induce glaciation[3], a point with which Cogley concurs. But his argument depends on variations in albedo contrast. Tarling maintains that adjacent seas are necessary to provide moisture for precipitation. In such conditions the mid-latitudes become sensitive to comparatively small changes in radiation such as those caused by variations in the Earth's orbit and the tilt of its axis[2]. However, contemporary theories of glaciation involve galactic mechanisms[4–6] only insofar as they influence the intensity of solar radiation. In what way can the reduction of solar radiation due to the Solar System passing through a dense galactic cloud (which has been shown to be related to the occurrence of ice epochs[4]) "modulate known tectonic mechanisms" here on Earth?

The distribution of the continents is evidently important. Oceanic current flow, cloud cover and atmospheric circulation, which ultimately determine the amount of heat absorbed, are all affected by continental drift. In the late Cenozoic era, Australia and Antarctica drifted apart, commencing around 55 Myr BP[3]. Circum-Antarctic oceanic circulation increased as the continental barrier was gradually removed with deep water flow occurring after the South Tasman Rise had subsided around 38 Myr BP[3]. After this time an increase in the extent of pack ice occurred with a profound effect on the Southern Ocean[3] and on polar albedo. Kennett also reports that equatorial oceanic circulation diminished during the Cenozoic because of the destruction of the Tethian Seaway and, slightly later, the blocking of the Indonesian Seaway.

On what grounds does Cogley assume that sea level has remained constant between 240 Myr and 0 Myr? Eustatic changes of up to several hundred metres have been proposed[7–9]. A quantitative assessment of changes of land area with latitude and with time cannot be made from maps of palaeocontinents delimited only by the present day shoreline[10]. For example, land areas on the North American continent in the late Cretaceous were at least 50% less than at present[9], a fact that cannot be derived from palaeocontinental maps which do not show any variation of coastline with time. Using Cogley's own formula (equation 1) the change in land area of North America alone would produce an increase in the average global absorbed radiation (about $1\,\mathrm{W\,m^{-2}}$) which is significantly greater than the variations he proposes through continental drift. Cogley states that the Mesozoic was warm, yet he presents a diagram of average global absorbed radiation over 240 Myr with a minimum (implying coolness) during the Mesozoic. If land area changes are taken into consideration, there should have been an increase in absorbed radiation.

Cogley should have considered the effect of clouds in more detail. Cloud plays a very important part in the global radiation balance[11] and determines the atmospheric transparency term in his equation 1. He has argued a dynamic model of glaciation from static components: from a snow-free world with contemporary cloud cover, from a world without changes of sea level and without pack ice. Albedo contrast may well play a part in initiating glaciation but the evidence cited does not support Cogley's thesis.

COGLEY REPLIES—I take Reynolds' most important point, that my model is simple while the world is complicated. I do not claim that the model is a comprehensive theory of glaciation; I say merely that physical reasoning leads us to expect a palaeoclimatic signal due to albedo contrast, and that if we could find it this signal would deepen our understanding of glaciation. Reynolds is entitled to reject my interpretation of Fig. 1*c* of my letter. He seems to have no quarrel with the concept of albedo contrast, but to claim instead that the signal is likely to be swamped by other effects. This would not surprise me in the least, and I look forward to accurate estimates of these effects.

Matters Arising

Matters Arising is meant as a vehicle for comment and discussion about papers that appear in *Nature.* The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted. Neither contribution nor reply (if one is necessary) should be longer than 300 words and the briefest of replies, to the effect that a point is taken, should be considered.

Many palaeogeographic effects are consistent with my model. A tropical clustering of landmasses surely suggests reduced tropical, and enhanced higher-latitude, meridional circulation in the oceans[1]. Kennett's evidence for sea ice, found in Southern Ocean sediments after 38 Myr BP, is not in conflict with what I deduced from the concept of albedo contrast. Note that I made no attempt to model the transition to glacial conditions; by design, my radiative calculations were for a snow-free world without pack ice, a state of affairs for which the apparently almost complete absence of glaciogenic rocks in the Mesozoic[2,3] provides circumstantial evidence.

I am unable to comment further on galactic mechanisms; my use of the verb 'modulate' was unthinking.

I assumed constant sea level because I wished to proceed from the simple to the complex. Maps of ancient shorelines carry uncertainties of their own[4], and the only global set[5] is 30 years old; although it was carefully compiled, it needs updating. One should be clear as to how continental flooding bears on my model. To nullify the concept of albedo contrast, flooding would have to be strongly biased towards either high or low latitudes, but such a bias is not seen. I fully agree that flooding may be important in its own right, and will affect my numerical results; I have indeed repeated the procedures of my letter for a series of equal-area maps based on the Termier and Termier set[5], but I am not yet able to discuss these results.

I agree also that clouds deserve thoughtful attention, but I emphasise again that my extremely simple model remains physically sound. I suggest that the time is ripe for modelling Phanerozoic climates at finer scales of resolution, and in increasing detail. However, I would caution that efforts at improving accuracy[6] should keep pace with speculative insight.

BOOK REVIEWS

Changing views of man

Antony Flew

Scientific Models and Man: The Herbert Spencer Lectures, 1976. Edited by Henry Harris. Pp.102. (Oxford University Press/ Clarendon: Oxford, 1979.) £5.95.

THIS slim volume consists of five of the six 1976 Herbert Spencer Lectures, a paragraph of Preface, and an Index. There are five only because the sixth lecturer, whom the Editor does not scruple to name, produced no script. No information about the contributors is provided, and there are more misprints — none of these sense-destroying — than one expects under the Oxford imprint. The Editor does not quote the terms of reference under which the lecturers worked. But, speaking presumably for the electors, he does say: ". . . we have gathered together a group of distinguished men from different disciplines to tell us how current work in their own subjects is changing their views of man".

The first essay, by Amartya Sen, is "Rational fools: a critique of the behavioural foundations of economic theory". The target in Sen's sights is that theoretical fiction, economic man; who is, by definition, "actuated only by self-interest" (page 1). But he seems not fully to appreciate how drastically this fiction is itself changed if you then proceed "to define a person's interests in such a way that no matter what he does he can be seen to be furthering his own interests in every isolated act of choice" (page 5). For a person who is thus necessarily in every choice striving — as the economists say — to maximise his own utilities may well be — in the everyday sense — acting very disinterestedly. What Sen explores is the huge area in which actual behaviour, though necessarily maximising the agent's utilities, is by no means reducible to the pure pursuit of that agent's self interest, as ordinarily construed.

In "Psychology and the image of man", Jerome Bruner confesses that in working on his lecture he was "drawn to a disturbing conclusion on the matter of why experimental or academic psychology had not had more of an impact on the broad cultural conception of the nature of man . . ." (page 27). I now confess that, having read the resulting lecture, I am more than ever inclined to think that the reason is that it has had nothing to say that should be of general interest: the genuine discoveries have no wider implications; while the claims which do have a shattering impact are not supported by the empirical work. Skinner, for instance, denies the reality of human choice and human purpose. But these claims are what he mistakes to be presuppositions of any science of psychology. They neither are nor could be findings of his own studies of rats and pigeons.

In "Memory and its models" J.Z. Young writes: "The concept that the brain contains information in a code is the new scientific model of memory, which I believe is revolutionising our view of man" (page 45). I am thus startled to be made to feel that I have all my life been a child of the revolution. For I cannot recall ever believing that information is stored in the brain in the form in which it is remembered. How could it be?

"Machine models of perceptual and intellectual skills" by Donald McKie is fascinating stuff: "The world has a false belief about calculating prodigies, namely that they calculate prodigiously" (page 74). The truth is, apparently, that they use all manner of calculation-saving dodges. The same is true of chess-masters: they neither do nor could work through every thinkable alternative many moves ahead. To achieve a Grandmaster level of play by a computer program on these lines: "It would . . . take of the order of 10^{90} years' continuous running on a super-fast machine to select a move" (page 77). For the benefit of possible philosopher-readers of *Nature* I have to mention the suggestive treatment of the seventeenth-century Problem of Dr Molyneux: "R.L. Gregory studied just such a case, in which the patient had had sight conferred on him by an operation of corneal grafting" (page 62).

In excellent taste, the most exciting contribution is kept till last. In "The universe as artefact", D.H. Wilkinson ponders Einstein's homespun question: "What does a fish know about the water in which he swims all his life?" (page 80). Wilkinson's ponderings raise questions about ways in which the basic facts about our nature — size, length of life-cycle, and so on — must eventually limit our possible physical knowledge: ". . . already in the big sciences it takes typically 5 years from inception to completion of an experiment . . . When we get to 100-year long experiments which have to be passed from academic father to academic son we shall not have many takers . . ." (page 82). But I wish that Wilkinson had ended, not by first mentioning and then repudiating Berkeleyan idealism, but with his earlier words: "'Perhaps the impossibility of finding quarks is Nature's way of letting us know that we have reached the end of the line.' But we know that we could not accept that." (page 97). □

Antony Flew is Professor of Philosophy in the University of Reading, UK.

Crossbridge theory in the dock

R.M. Simmons

The Molecular Basis of Force Development in Muscle. Edited by N.B. Ingels. Pp. 162. (Palo Alto Medical Research Foundation: Palo Alto, California, 1979.) $17.

THE sliding filament theory of muscular contraction is generally accepted as well established. Less certain is the mechanism of force generation and shortening, but the great majority of workers in the field accept some form of crossbridge mechanism at the very least as a working hypothesis. There are dissidents from the majority view. This book, the proceedings of a conference held in Miami in 1977, is edited by one of them and the conference evidently served as a platform for the views of another (Pollack). Perhaps court-room would be more appropriate than platform, for Pollack seizes the roles of prosecutor, judge, jury and would-be executioner, with orthodoxy embodied by H.E. Huxley, Podolsky, Weber and Julian in the dock.

The trial opens with short pleas from the defendants. The case is nicely argued on the grounds of structure (Huxley and Podolsky), biochemistry (Weber) and mechanics (Julian and Podolsky). The prosecution case from Pollack, subsequently enlarged on in a lengthy cross-examination of the defendants, involves two main charges. The first is that the constancy of filament length demanded by the sliding filament theory is not always to be found in the literature, but Pollack's attempt to weigh the evidence by number of pages rather than by scientific merit becomes more of a trial of patience than of fact. Huxley defends the case as trenchantly as he did twenty years ago and the theory emerges from the trial without much of a stain on its character. The second charge concerns the length-tension relationship, one of the corner-stones of the crossbridge hypothesis. Gordon, A.F. Huxley and Julian showed in 1966 that the tension developed by a muscle fibre depends linearly on the overlap between the filament, though if stimulation of stretched fibres is prolonged tension continues to rise slowly. This was ascribed to the shortening of some of the sarcomeres. Pollack states that he does not observe such a shortening, at least using light diffraction. On the other hand Julian says he does, using photography. A fair verdict would be that the charge is "not proven."

Ingels makes what seems to be his second contribution to the field with a chapter on "Unifying Concepts" which attempts to unify his first contribution, a non-crossbridge theory, to crossbridge theory, but little else. As organiser of the conference he must bear some responsibility for the fact that nearly two-thirds of the book is unrepresentative of current research in the field. The chapters on crossbridge theory and practice might serve as an introduction to the field and contain some new results particularly from X-ray diffraction studies, but they are too brief. The discussion never gets away from the two issues reported above. The question of whether current results from structural, biochemical and mechanical studies can be explained on other than a crossbridge model is not raised. There is an Appendix from Ingels with a chronology of muscle theories, some of which are splendidly batty. □

R.M. Simmons is Lecturer in Physiology at University College, London, UK.

Molecular basis of tumourigenicity

Dennis D. Cunningham

Surfaces of Normal and Malignant Cells. Edited By R.O. Hynes. Pp.471. (Wiley: Chichester, UK, and New York, 1979.) £24.

THE cell surface has become a prime target for studies on the molecular basis of tumourigenicity. In a lucid introductory chapter, the editor summarises reasons for this, discusses issues basic to such studies (for example, do properties of transformed cells in culture accurately reflect the properties of malignant cells *in vivo*?), and sets the stage for the subsequent contributions.

A chapter on morphology of normal and transformed cells is followed by three chapters on cell surface composition which emphasise glycolipids, proteins and glycoproteins, and mucopolysaccharides. Two chapters focus on enzymes of normal and transformed cells, and there is a chapter on immune responses to C-type virus-induced tumours. From here on, the chapters mostly deal with control processes in normal cells: early events in growth stimulation, surface transport components of erythrocytes, adhesive specificity among embryonic cells, and the cell surface and development in the cellular slime mould *Dictyostelium discoideum*.

A theme which recurs in this volume is that the several properties which appear to correlate generally with the transformed state are not invariably found in all transformed or tumourigenic cells; it is probably certain combinations of these, along with alterations yet to be defined, that collectively underlie malignancy. Given present uncertainties about which of the many alterations found in transformed cells and their surfaces might be causally related to malignancy, and the fact that any given topic on regulation of cellular activities could relate to alterations basic to malignancy, the editor faced a real challenge when choosing the issues to be addressed in this volume.

Although most of the choices were excellent, it would have been an easy matter to justify individual chapters on assays for tumourigenicity (malignancy?) of cultured cells, and the use of melanoma lines with specific metastatic potentials to probe cell surface properties related to metastasis. As emphasised by the editor, the commonly used assays for tumourigenicity of cultured cells depend on growth and survival of the cells and not generally on their ability to invade and metastasise, even though the latter two properties distinguish malignant tumours from ones that are benign.

As "a mere collection of data would soon become out of date . . . the authors were encouraged to extrapolate from the established facts and discuss hypotheses concerning their significance". As a result, the individual chapters are generally conceptual in nature, and provide the reader with interpretations of results. Thus, the volume does what this type of book should: synthesise and extrapolate rather than present previously published data. At the same time, each chapter is quite well referenced, providing the reader with ready access to the original literature. In general, the individual chapters are well written and the authors emphasise questions that remain to be answered. Two chapters, "Surface Membrane Enzymes in Neoplasia" and "The Cell Surface and Development in the Cellular Slime Mould *Dictyostelium discoideum*", were disappointing. Both were rather long on facts and short on interpretation. Unfortunately, the latter chapter did not contain a much needed summary section.

My overall impression of this book is quite favourable. It generally emphasises ideas and questions; at the same time, it contains enough experimental facts to be informative and credible. With exceptions in only several parts, the book is well integrated, a feature which should increase its general appeal. □

Dennis D. Cunningham is Professor of Microbiology at the University of California at Irvine.

Wave functions for atoms and molecules

A.D. Buckingham

The Calculation of Molecular Orbitals. By J.C. Slater. Pp. 104. (Wiley: New York and Chichester, UK, 1979.) £11.50; $23.

PROFESSOR J.C. Slater was a theoretician of the first rank and a prodigious writer of textbooks. The present work is the last in a series of eight books by Slater on the quantum theory of matter (the first was published in 1960). The manuscript of this book was found among his papers following his death in 1976, the only addition being a list of a small number of references.

In the last ten years of his life, Slater was concerned with the local-density form of the self-consistent field; his work led to the so-called $X\alpha$ method, and he and many others applied it to a wide range of problems in theoretical physics and chemistry.

This new book of only a hundred pages centres on the SCF $X\alpha$ method for obtaining approximate electronic wave-functions for atoms and molecules.

Applications of the $X\alpha$ method have involved approximations which impose limitations on the validity of the results. Slater's purpose in writing this book was to suggest a different scheme for solving the SCF equations. He turned to the cellular method, developed by Wigner and Seitz for handling the problem of computing the orbitals of a crystal. (Slater himself was a pioneer in this energy-band theory.)

All those who are interested in the SCF $X\alpha$ method will find this a most useful and informative book. It is the writing of a mature scientist, one of the masters of theoretical physics and chemistry. □

A.D. Buckingham is Professor of Chemistry at the University of Cambridge, UK.

Single-stranded DNA phages

Mary R. Lunt

The Single-Stranded DNA Phages. Edited by D.T. Denhardt, D. Dressler and D.S. Ray. Pp.720. (Cold Spring Harbor Laboratory: Cold Spring Harbor, New York, 1979.) $49.

IT is now twenty years since Sinsheimer wrote that finding a single-stranded DNA molecule was "like encountering a unicorn in the ruminant section of the zoo". Since then studies on the single-stranded DNA phages have not only produced information relevant to fundamental biological processes but have contributed much to the development of methods now routinely applied in protein and nucleic acid biochemistry.

This book arose from an international meeting held in August 1977, but includes references to papers and unpublished work up to 1978. The articles are comprehensive and well-written reviews of all aspects of the biology of the single-stranded DNA phages. They include discussions of the structural and regulatory roles of the protein-nucleic acid interactions involved, thus providing interest well beyond the specialist areas considered.

The papers mainly refer to the isometric phages ϕX174, S13 and G4, and to the male-specific filamentous phages f1, fd and M13. They all use *Escherichia coli* as host and have virions which contain single-stranded, covalently closed, circular DNA of molecular weight about 2×10^6 and coding for nine genes. Besides being the first virus shown to contain such DNA, ϕX provided the first example of overlapping genes, that is, regions in which the DNA codes for more than one protein, the RNA transcripts being read in different phases. There are articles giving the complete nucleotide sequences of ϕX, G4 and fd DNAs, and discussions of the gene assignments and gene functions. The filamentous phages do not have overlapping genes, and can package variable amounts of DNA, as described in the use of M13 as a cloning vector.

The chapters on DNA synthesis review the many elegant experiments on the structures of the replicating forms, and their reproduction *in vitro*. The general significance of these studies is apparent in their analysis of the probable roles of host proteins in bacterial DNA synthesis, and also in their revelation of the importance of DNA secondary structure and its modification by enzymes such as DNA gyrase, helicases and the *E. coli rep* protein.

The analysis of transcriptional control of protein synthesis by these phages has revealed their ability to make a variety of polycistronic RNAs in which sequences coding for proteins made in large amounts appear in more than one RNA species. There are discussions of the structures recognised by RNA polymerase at initiation and termination sites, now made possible by the availability of DNA sequence data.

Increasing attention has recently been given to the formation of intact virions. The isolation of ϕX precursor particles is described and the protein-DNA interactions are discussed. The intriguing production of filamentous phage particles without cell lysis now seems to present an example of the 'signal' mechanism, as nascent coat protein molecules are probably embedded in the cell membrane by way of a leader sequence, the final protein product exchanging with the intracellular DNA binding protein as the phage DNA is extruded from the cell.

The chapters on filamentous phage virion structure provide detailed discussions of diffraction and other data which support different models for the spiral arrangement of protein monomers around the central DNA. There are also accounts of the use of single-stranded DNA phages in the analysis of genetic recombination, and of the disruption of virion structure which occurs when ϕX particles adsorb to the host cell.

The book is not for beginners, but it contains much which can be appreciated and enjoyed by advanced undergraduates and those who teach them. □

Mary R. Lunt is Lecturer in Biochemistry at the University of Oxford, UK.

Vitamin D metabolism and function

R.H. Wasserman

Vitamin D. By H.F. DeLuca. Pp.80. (Springer: Berlin, New York and Heidelberg, 1979.) DM29; $15.

VITAMIN D has long been appreciated as the primary factor required for the prevention and cure of rickets and osteomalacia in man and animals. This factor, acquired exogenously or synthesised endogenously by the skin upon exposure to UV light, undergoes biochemical transformations to yield various metabolites, including those hydroxylated in the 25 position [25(OH)D], in the 1 and 25 positions [e,25(OH)$_2$D] or in the 24 and 25 positions [24,25(OH)$_2$D]. The 1,25(OH)D has recently become recognised as a bona fide hormone since it affects reactions elsewhere than at the site of synthsis (kidney) and is under feedback control.

The biological effects of vitamin D and its metabolites have been extensively studied in recent years, and a considerable amount of new information and concepts on this aspect have also become available recently. Among these are the protein synthetic theory of vitamin D action, the identification of several proteins induced or modified by steroid repletion, the interaction of metabolites with the intestine, kidney and bone, and with organs not traditionally considered to be targets, such as the parathyroid gland and pancreas, and details on the translocation of calcium and phosphate across epithelial membranes, to mention just a few.

H.F. DeLuca has gathered together and integrated in a short monograph much of the recent advances. Specifically discussed in this volume are historical aspects, the chemistry of precursors and metabolites of vitamin D, the biological control of the formation of vitamin D by nutritional and hormonal variables, the molecular events affected by vitamin D that bear on calcium and phosphate metabolism, and therapeutic experiences with vitamin D and its metabolites.

Of considerable value are the critical analyses by the author of present concepts and of various published studies. Areas in which there is a paucity of information, and where controversy abounds, are frequently noted. However, not all experts in the field will agree with some of the interpretations and viewpoints of the author, perhaps an expected spin-off of a very active research area. For this reason, the reader is urged to consult other recent reviews and monographs on this topic in order to obtain a broader perspective.

The monograph is well written, lists about 400 references, and is reasonably well illustrated. Since the author and his associates around the world have been prolific contributors to vitamin D research, this monograph in a sense represents a cataloguing of their many contributions (about 30% of the references cited are authored or co-authored by Professor DeLuca).

This monograph should appeal both to the specialist on vitamin D, calcium and phosphorus metabolism, and to the interested non-specialist. It should also prove useful to the clinician, providing an introduction to the chemical and biological behaviour of a class of compounds that are efficacious in some disease states and potentially therapeutic in others. □

R. H. Wasserman is a Professor in the Department of Physical Biology and Section of Physiology, New York State College of Veterinary Medicine, Cornell University, Ithaca, New York.

Basic biology of *Drosophila*

Peter Lawrence

The Genetics and Biology of Drosophila. Vols 2a, 2b and 2c. Edited by M. Ashburner and T.R.F. Wright. (Academic: London, New York and San Francisco, 1979.) Vol. 2a: £28.50, $59; Vol. 2b: £29.60, $61.25. Vol. 2c: £32, $74.

ASHBURNER and Wright is a mammoth read. Or is it? This is the question for the *Drosophila* worker: Are the three parts of this volume a handbook for reference or a collection of ephemeral reviews for reading? If the former then the Drosophilist will want to buy them (or, rather, prefer to beg or steal them as they cost nearly £90). If the latter, then a lending library can be relied on and the relevant chapters read. It is not clear what the editors would have their books be. They write that it is an attempt "to gather together as much information on the basic biology of *Drosophila* as possible excluding only its formal genetics found in volume 1 and its population biology to be covered in volume 3".

I think these books deserve to be judged by high standards and to me that means as a handbook, a book which no *Drosophila* worker can be without because it contains the basic facts and methods. A handbook should make accessible the present state of hard knowledge, where the literature is critically distilled and not merely catalogued. This is especially true with *Drosophila* where an indexed bibliography is available. Just as important, the methods, hints, tricks and ploys should be given special emphasis. In brief, the chapters of a handbook should be written with the readers' needs in mind. By contrast, in reviews, the author is frequently thinking of making some kind of a sale.

As these three books have, necessarily, been written by many authors, it is no surprise that this purpose is not achieved by all, or even by most. Some chapters are, and will be, extremely useful — others are already out of date or just forgettable. The useful or essential chapters are mixed up with the relatively useless ones; the topics are also randomly assorted. This means, of course, that we have to buy each volume even if we need only a small part of each. For example, to obtain the critical review on chromosome puffing the cytologist has to pay for what is in effect a 150 page monograph on behaviour — this topic is unlikely to be close to his, or her, heart. One wonders whether this is one reason why big multiauthor books are becoming so popular with publishers — a small number of desirable pages can sell a larger number of undesirable ones. Always true of journals but not, in the good old days, true of books.

As I read through volume 2 it was not always easy to discern editorial purpose. The chapters are often of profligate and arbitrary length. Why, for example, should we have the same number of pages (100) on mutants which produce tumours (at the moment a somewhat unclear and peripheral subject for most Drosophilists) as on the central technical matter of chromosome aberrations (Volume 1)?. Why so much on the field of imaginal disc development and its genetics? This field is interesting, but it is moving just too fast to be reviewed at such length in a handbook. Thus, because of long publication delays, the chapters on this topic are already becoming obsolete (from the literature references I get the impression that they were written about 3 years ago). By contrast, the scanning electron microscope atlas of the fly will be useful to many and retain its usefulness for years. The collation of culture methods is admirable and here one can detect the special atmosphere of free exchange of know-how and stocks, which is such a pleasing aspect of work with the fruitfly.

In these books there are chapters on all manner of things: culture methods, both of flies and cells; nutrition; enzyme genetics; visual physiology; behaviour; tumours; chromosome puffing; the blood system; muscles; the fat body; malpighian tubules; ageing; embryonic development; imaginal discs and transdetermination. This means that every fly worker will want to read some parts and others will need to have the books within easy reach of their microscope. However, one cannot help feeling how much better they could have been. The chapters could have been more logically grouped. Ephemera could have been more conscientiously avoided. If the authors had been limited to numbers of pages which correlated with the importance of their subject, could this volume not have been at once shorter, cheaper and more valuable? □

Peter Lawrence is on the staff of the MRC Laboratory of Molecular Biology, Cambridge, UK.

Mechanisms of cell killing by radiation

J.H. Hendry

Cellular Radiobiology. By Tikvah Alper. Pp.320. (Cambridge University Press: Cambridge and New York, 1979.) Hardback £18; paperback £5.95.

THIS book would be more aptly titled '*Mechanisms in Cellular Radiobiology*' or more specifically '*Mechanisms of Cell Killing by Radiation*'. Written by one of the leading and often controversial figures in this field for a quarter of a century, the book traces in depth, both historically and scientifically, our knowledge of how various radiations cause a loss of reproductive integrity of cells when irradiated in different conditions.

It is the only book in recent years to compare and contrast fully and with clarity the response of different cell types from bacteria to mammalian cells, and it is this comparison which has provided much of our insight into the mechanisms of radiobiological effects. As the latter have not yet been fully elucidated, this has prompted hypotheses such as target theory and repair models to 'explain' dose–response relationships. These are discussed at length both in the first few and in the last few chapters. Sandwiched in between are the observations concerning dosage modifications caused by radiosensitisers (primarily oxygen), radioprotectors, ionisation density, phase of the cell cycle at which cells are irradiated, dose fractionation, and dose-rate effects.

The failure of target theory to accommodate certain critical radiobiological findings has led to the clear conversion of the author from target theory to repair-type models which are less rigid in their constraints. Perhaps as a consequence the correlation between chromosomal injury and cell lethality, now convincingly demonstrated, receives little attention. The treatise of repair-type or pool models is novel and comprehensive.

The book concludes with a chapter on measurements of cell survival *in vivo*, which is purposefully concise but which is consequently not as comprehensive as the other chapters. Also, in a few instances, effects are discussed which have not generally been found by other investigators, for example, aspects of survival and dose-rate effects in bone marrow.

Although there are many useful tables of collated data, this is clearly not simply a textbook for learning by rote. It is more a stimulating thesis to be digested, argued, even attacked, and will undoubtedly remain a firm favourite with mechanistic radiobiologists. In contrast to nearly all other specialised texts, the provision of a separate paperback edition puts this volume within everyone's pocket. □

J.H. Hendry is Head of the Department of Radiobiology in the Paterson Laboratories at the Christie Hospital and Holt Radium Institute, Manchester, UK.

OBITUARY

Peo Koller

P. C. Koller, Professor of Cytogenetics at the Institute of Cancer Research, died on 29 June 1979. He will always be remembered by those who knew him well. For some it will be his splendid humour that endeared him, for others his fascination for the facts of life.

Born in 1904, he was taken as a novitiate into a Benedictine community at the age of twelve with the intention that he should eventually become a teacher in a subject that he found pleasing. Choosing botany and zoology he eventually graduated from the University of Budapest in 1924 at the age of 20. During his time in the monastery and university he had had to combine religious and scientific studies and it is clear from what he wrote in his unfinished autobiography that there arose in his mind, even before he graduated, some difficulties of reconciliation of the two disciplines. Despite this he was ordained into the priesthood the same year he gained his BSc.

Rather to his surprise his superiors offered him a teaching post in Budapest and encouraged him to undertake a PhD. He met a number of scientists including Voronow, Rhoda Erdmann and Kammerer at an International Conference in Budapest in 1927 and became committed to a research career. Shortly after joining the new hydrobiology unit at Tihany on Lake Balaton he was granted a scholarship to go to Cambridge in the United Kingdom.

This was the beginning of his break with the church which was in a large part due to increasing interest in genetics. As he explained it, the determinist philosophy of genetics, with which he became involved under the influence of his collaborators T.H. Morgan, Theodore Dobzhansky, C.D. Darlington and H.J. Muller, was the deciding factor. His interests turned specifically to cytogenetics which was a newly emergent discipline in the early 1930's. During and immediately after the war he became involved with the effects of alkylating agents, such as nitrogen mustard, on chromosomes, an interest which remained for much of the rest of his working life. He joined the staff of the Royal Cancer Hospital and soon afterwards its pup, the Chester Beatty Research Institute.

Peo's study of chromosome breakage in tumours particularly under the influence of cancer chemotherapeutic agents established him as a leading authority in the field. At that time, however, further and more exact developments of cytogenetic studies of mammalian somatic chromosomes was somewhat hampered by the inadequacies of the available methods.

In 1956 under the influence of Alex Haddow he became interested in the newly discovered radiation chimaeras, the analysis of which was best accomplished by cytogenetic methods with which Peo was familiar and which, largely under the influence of Peo's friend, Charles Ford, were now more reliable.

Peo's curiosity led him with enthusiasm into the fields of haematology and immunology which emerged as integral parts of the study of chimaerism.

He was a great biologist and always had the ambition that biology should be accepted in its own right as a major discipline in cancer research. In his latter working years he provided encouragement for a number of young research workers including J.F.A.P. Miller who made his discovery of the function of the thymus whilst under Peo's umbrella.

He rarely scolded his juniors and always provided the quiet and unobtrusive support which is so successful and so difficult to emulate. It should not be thought that he lacked in passion. His occasional anger was a source of amazement and delight to his colleagues who, on one occasion at least, had to shelter from bombardment with the bottles in which *Drosophila* flies were kept.

Peo found great happiness in his marriage and his three daughters were a constant source of delight and pride in his life.

After retirement he became an articulate and much-respected member of the rural community in which he and his family chose to live. His preaching there of the delights and method of biological science was probably in many ways the happiest time of a very full life.

He will be remembered with affection and gratitude by his friends, his colleagues and his neighbours. There was rarely a dull moment with Peo about.

Tony Davies

C.E. Wynn-Williams

Dr Wynn-Williams, a pioneer in the use of radio valves, valve amplifiers and thyratrons for measurement and counting in the fields of nuclear and radiation physics, and in the basic techniques of electronic computers, died at his home near Aberystwyth on 30 August 1979, aged 76 years.

He was born in Swansea on 5 March 1903, attended Wrexham Grammar School and entered the University College of North Wales at Bangor in 1920 with an Open Scholarship and a County Exhibition. He received the R.A. Jones Mathematics prize in 1922 and graduated BSc Wales with first-class honours in physics in 1923. From 1923 to 1925 with the aid of a Research Studentship of the University of Wales he carried out research at Bangor under Prof. E. Taylor Jones, obtaining an MSc Wales in 1924.

He then continued with research in physics, at the Cavendish Laboratory, Cambridge, under Sir Ernest Rutherford, with, in succession, a University of Wales Open Fellowship, an 1851 Senior Fellowship and a moiety of the Clerk Maxwell Studentship. During this period he took a BSc London with first-class honours and received a Cambridge PhD in 1931.

His first two papers relating to valve amplification described a valve amplifier for ionisation currents with compensation for L.T. and H.T. battery fluctuations and equivalent to a quadrant electrometer of sensitivity more than 6000 mm per volt; and with the modifications of this necessary to allow it to be applied for measuring X-ray and photo-electric effects. He next worked in collaboration with Cave and Ward on the rate of emission of α-particles from radium, and with Rutherford and Ward on the α-rays from RaC, ThC and AcC, his main contribution being the design of the valve amplifier for the detection of the individual particles and its screening from outside effects.

A visit to the Cavendish Laboratory by A.W. Hull about the time of Hull's full description of thyratrons in 1929 stimulated Wynn-Williams' interest in them and led to his first step in their applications to counting when he devised a ring of four thyratrons and applied it in 1931 to further α-ray counting experiments with Rutherford and Lewis, in the investigation of long-range α-particles from ThC and AcC.

In the following year he published his "scale of two" thyratron counting system which, he pointed out, could be operated by current taken from the ordinary A.C. mains supply and required no delicate adjustments; it was this invention, followed six years later by a somewhat similar counter devised by W.B. Lewis emplying hard valves instead of thyratrons, from which has mushroomed the great technology of digital electronics. In recognition of this work Wynn-Williams was awarded the Duddell medal of the Institute of Physics in 1957.

During the second world war Wynn-Williams was deeply involved in the work of code-breaking machines, in particular on the "Enigma" cipher machine and on the electronic side of the "Heath Robinson" cryptanalytic device which was a step towards the later wholly successful "Colossus" machine. It is believed that he was at least in part responsible for the securing of T.H. Flowers and his team from the Post Office Engineering Research Station at Dollis Hill for the cipher work at Bletchley Park.

After the war, Wynn-Williams returned to Imperial College and threw himself whole-heartedly into teaching work in practical physics in which his great inventive skills and warm personality led to outstanding success.

The author of this obituary experienced these personal qualities to the full during the three years in which he was associated with Wynn-Williams at Cambridge and cannot speak too highly of him as a co-worker and friend, and for his help and encouragement.

F.A.B. Ward

Vladislav Kruta

MANY physiologists and historians of medicine in France, Great Britain, Czechoslovakia, and as far afield as New Zealand will be sorry to hear of the recent death of Professor Vladislav Kruta, MD, DrSC, past director of the Institute of Physiology of the Purkyně University in Brno, Czechoslovakia.

Born in 1908, his scientific career started in the early thirties at the Department of Physiology of Charles' University in Prague. From the beginning his interest was focused on the comparative physiology of heart muscle and on the effects of temperature on contractility. His research on the "Bowditch staircase" became a classic. His work brought him into close contact with French physiologists and especially with the school of Professor Lapique, where he spent a long period and where he also met his future wife. These contacts gave Czech physiologists access to the French and Western scientific forum: as a General Secretary of the Czechoslovak Biological Society he made this society a branch of the old and famous French Societé de Biologie.

As a convinced democrat, he left Czechoslovakia before the Second World War, spent a difficult period in France and was transferred after the fall of France with the Czechoslovak troops to Great Britain. As a medical officer, he became attached to the famous 312th Squadron of the Royal Air Force, composed mostly of Czechoslovak airmen, a squadron which won its glory during the Battle of Britain, with the loss of many lives. For his courageous conduct, Kruta was awarded one of the highest Czechoslovak military medals. Later in the war he was transferred to the Ministry of Social Affairs of the Czechoslovak Government in exile (in London) where he made use of his vast knowledge of the problems of nutrition to prepare the way in which the assistance of UNRRA should be made use of in his liberated home country. Czechoslovakia owes him gratitude for the generous contribution of UNRRA in reopening and restarting medical and biological research after the war.

In 1945, Kruta became one of the founders of the new medical school in the city of Hradec Králové. As with many other people who fought in the Allied forces in the West, he had been persecuted since 1948 and dismissed shortly afterwards from the Hradec Králové medical school, when it became a military medical academy under Russian supervision. He then took over the Chair of Physiology at the Purkyně University of Brno. In spite of many obstacles of a political nature he created there an excellent modern school of physiology, concentrating mostly on experimental cardiology.

His classical education and early interest in general history led him later to the history of medicine and mainly to the two great Czech protagonists of physiology — Procháska and Purkyně. It was Kruta's great achievement to continue and complete the edition of Purkyně's *Opera omnia*, started before the War by the Prague histologist Prof. Studnička, and to write a monograph on both these great figures.

During the Prague Spring in 1968, Kruta deeply engaged himself in the democratization of life in Czechoslovakia. He was one of the 70 original signatories of the manifesto of "2000 words" and after the Russian occupation, and in spite of pressure, he refused to recall his signature. This led to his immediate dismissal from the chair and from all academic activities. As a private person he continued his historical studies. His courageous and honourable life made him a lasting model to his compatriots and friends.

Jan Brod
Otokar Poupa

Robert Heizer

ROBERT FLEMMING HEIZER, who died on 16 July 1979, at the age of 64, was one of the best known and most outstanding archaeologists to have been trained and who taught at the University of California at Berkeley.

His contributions to his profession, to the scholarly world, to the public in general and to his University were continuous and at an extraordinary and prodigious rate and level of creative excellence that is rare, even in the most distinguished communities of scholars. He was the author of 24 books and nearly 400 scientific articles and monographs that express the remarkable breadth and wide-ranging interests of California's pioneer scientific archaeologist who believed that it is impossible to understand mankind or to formulate "laws" of culture without using the data of prehistorians.

Ranging from book-length treatments of the Olmec civilisation of Meso-America or the prehistoric rock art of California and Nevada (on which he was the acknowledged authority) to a study of prejudice and discrimination against Californian minorities under Spanish, Mexican and US regimes, or X-ray fluorescence analysis of obsidians and replicative experimentation in archaeology, his work also included excursions into such subjects as toxicology, geology, mineralogy, organic chemistry, pedology, demography, mathematics, architecture, history, limnology, law, conchology, zoology and economics, wherever he believed they could throw light on past human behaviour. His investigations at La Venta, not far from the Gulf of Mexico, as well as in the Valley of Mexico and Guatemala led him to develop a keen interest in the transport of megalithic monuments and the methods of erecting them which resulted in a brilliant piece of research on the origins of the Colossi of Memnon on the Nile.

The quantity and quality of his research and publication may in time tend to obscure his work and ability as a teacher. In this, however, he was equally successful and an inspiring lecturer at all levels of instruction. His teaching ranged from North American and Meso-American archaeology to California Indians, archaeology and society, and science in archaeology and he was equally as successful in field courses as he was in the classroom and in seminars. He was always available to talk with students, especially with any who came to discuss their original ideas.

Heizer's work is both the foundation on which systematic archaeology in California has been based and a contribution of major significance for the science of archaeology in general. This was recognised in the honours conferred on him: he was elected to the Society of Sigma Xi, was twice a Fellow of the Guggenheim Foundation, a Fellow at the Center for Advanced Study in the Behavioral Sciences at Stanford and was elected a member of the National Academy of Sciences in 1973. He received an honorary ScD from the University of Nevada in 1965.

Bob was the kind of scholar who will not be seen again for a long time. He was a great archaeologist to whom prehistory in the western states will forever be indebted. He was possessed of a rather rare sense of humour and could be extremely witty and good company. Critical of others, he was equally critical of himself and in some ways was a "loner". His friends remember him for his humour, kindness and generosity, his students for the way he shared with them the excitement of new discoveries in the field and colleagues and students alike for the magnitude and depth of his scholarship and for the stimulus that he gave to the discipline in general.

Biotechnology back in the limelight

A FEW years ago — in the mid to late 60s — there grew up a fashion for thinking that the 'new biology' would revolutionise the chemical and pharmaceutical companies. It has made its impact, but not so great as was first promised. Now again the genie rises, to face a number of problems — which we outline on pages 122-131.

The first flowering came with the elucidation of the sequences, structure, and function of a few enzymes, and their immobilisation to act as efficient, recoverable industrial catalysts, so that it became conceivable that all biology could be tamed and put to work. It affected mainly enzymologists and microbiologists. The second follows the discovery by molecular geneticists of techniques for manipulating and transferring DNA between organisms, and it has led to that new group of biologists discovering something quite different: the profit motive and the ways of industry.

Problems and acrimony have arisen between the biologists and industry, and among the biologists, particularly over the question of confidentiality. Scientists with one foot in the academic and one in the business world have felt a conflict between the need to publish fast and first in the former, and to keep secrets and respect patent law in the latter. In some of the smaller business ventures the urge to publish appears to have been effectively quashed; in others, it survives, if not completely intact.

Secrecy means that some academics cannot disclose to their colleagues the details of industry-funded research that is going on in the lab next door — souring relationships between them. For example the silence from most of the laboratories competing fiercely to sequence, clone, and manufacture interferon has, at times, been complete. But that is not surprising when what used to be an innocent amino-terminal acid sequence can be the key to a fortune.

These problems, though, should be temporary. They come about because the firms need to draw on a new community of scientists, one that is used only to the priorities of basic research. But already a new breed of molecular biologist is emerging which concerns itself not so much with understanding basic mechanisms as with manipulating them to reach desired goals. The joys of mission-oriented research are totally different from those of simple inquiry, and slowly they will sort out a different kind of biologist, and eventually a different career structure, different opportunities and relationships. It was in just this way that the devices engineer became separated from the solid state physicist, and the nuclear power specialist from the physicists who play with quarks. The same will happen in biology.

The middle-term problem rests with governments: how to set up a productive biotechnological community involving both basic biologists and industry, so that interested biologists can 'get their feet wet' and solutions be found to real practical problems. As with any technology, there will always be a need for an academic bioengineering community dealing with long-range issues of only partial interest to industry, between the industry-based biologist and his or her fundamentally inclined colleague; it is for government — and the universities — to set up this community and ensure its proper recruitment, training, and regeneration. In the UK, it is to be hoped that the Royal Society committee currently inquiring into biotechnology will make recommendations on this matter.

But strangely the long-term issue rests again with the biologists. The physicists have learned, rather late, that their technologies have had an immense impact on society. That impact began with a certain selection of priorities, mainly by industry, which led physicists to research in one area rather than another. (Thus, for example, solid state physics was vigorously pursued because of its significance to the electronics industry, whereas oceanography was relatively neglected — until the need to detect nuclear submarines or search for minerals.) The same forces are undoubtedly at work now in biotechnology — and this is precisely the moment when patterns of research will be formed which will ultimately shape lives. Communities and laboratories will be set up in various targeted disciplines, some fields will be encouraged and others neglected; expertise and training will develop along lines which will later be difficult to change. It is an interesting moment for biologists: they have great power in their hands. Do they let the entrepreneur guide them, willy nilly, to the fastest return? Or do they, if ever so slightly, change his priorities? □

United States

David Dickson reports from the American Association for the Advancement of Science's annual conference in San Francisco.

New effort urged to control nuclear weapons spread

RECENT events in Iran and Afghanistan, and the domestic political response to these events in the US, have increased the need for scientists to support efforts to control the proliferation of nuclear weapons, a succession of speakers told a forum on ending the nuclear arms race.

Talking two days after President Carter had requested the US Senate to postpone its debate on the ratification of the Strategic Arms Limitation Treaty (SALT II), the speakers warned of the dangers of linking the nuclear weapons issue to broader political considerations of East-West relations.

"The present crises show that no security has been gained by massive nuclear arsenals. In fact the situation is only made more dangerous," said Professor Everett Mendelsohn of Harvard University. "I believe that scientists, who have been so especially involved in the design and construction of nuclear weapons and advanced missile systems, have an added responsibility to press for nuclear disarmament now. The scientific community has been too quiet for too long on the nuclear arms race."

Jeremy Stone, director of the Federation of American Scientists, emphasised that the importance of separating SALT from detente, as well as the whole logic of arms control, had never been so clear. "Supporters of SALT will have to, and should, separate their case for SALT from their case for detente. And SALT opponents will have to consider how far they want to go in giving up hopes for reducing the risks of nuclear war in order to ensure sharp US responses to Soviet adventures."

Reflecting the shifting political climate with respect to arms control, and military spending Dr Bernard Feld, editor-in-chief of the *Bulletin of the Atomic Scientists*, pointed out that the magazine had recently decided to move the clock on its front cover, an indicator of the world's proximity to nuclear destruction, from nine to seven minutes before midnight.

"This seemed an adequate gesture a few months ago, but after the recent events we should probably move it even closer, perhaps to five minutes to midnight," said Dr Feld. Reasons for the decision to shift the clock, which had previously remained unchanged since 1974, included the apparent breakdown in the SALT process and the spread of new nuclear weapon systems in Europe.

Professor Mendelsohn told the audience that a new *ad hoc* committee was being established to coordinate the lobbying efforts of scientists in pushing for nuclear weapons control, and urged that the AAAS council adopt a resolution recognising the importance of continued support for the SALT treaty. □

'Big brother' approach to space must go

THE US should support the efforts of the United Nations to forge an international consensus on the commercial uses of space, as this was the only way to guarantee long-term access to the markets being opened up by current research, according to Dr Jerry Grey, administrator of public policy for the American Institute of Aeronautics and Astronautics.

Referring in particular to a draft treaty of the uses of the moon approved by the UN General Assembly in New York last month, Dr Grey said that it was important for the US Senate to ratify this treaty, even though many scientists and industrialists had already expressed concern about some of the restrictions that it might place on the space activities of US corporations.

"If necessary, the US should express reservations in the process of ratifying the treaty. But we must hedge our bets as effectively as possible to ensure that our long-term interests are protected. We cannot afford to have the US barred from these activities as a result of charges of imperialism or of exploitation of the Third World," said Dr Grey.

He pointed out in particular that it was the US which had introduced the 'common heritage' language into discussion about the uses of space when the UN had first started discussing the issue in the early 1970s. Any other position than accepting the common heritage principle "would have seriously prejudiced US ability to conclude the cooperative agreements which are essential to US participation in potentially lucrative global markets," Dr Grey said. And awareness of this need among negotiators was one welcome sign that the US might be revamping its present "big brother" approach to global space applications.

In addition to the UN discussions, the recent successes of European space efforts emphasised how formerly sacrosanct US markets were being invaded. Unless policy-makers reversed their traditional reluctance to engage in cooperative activities, the US would almost certainly lose out on major forthcoming market opportunities. □

EPA wants more data on chemicals

UNLESS the chemical industry is prepared to present more substantial data on the health and environmental effects of new chemicals, the Environmental Protection Agency may have to take various measures — including if necessary temporarily preventing the manufacture of the chemicals in question — to ensure that adequate testing has been carried out, according to Dr Steven Jellinek, director of the EPA's office of toxic substances.

Dr Jellinek said that since the pre-manufacture notification requirement of the Toxic Substances Control Act had come into force six months ago, data on the testing of 51 new chemicals had been passed to EPA for approval. In examining these notices the agency had in particular found a tendency for companies to go for less expensive forms of tests, resulting in a relative lack of what EPA considered to be adequate safety information.

"In many cases, very little environmental or health data is included — for example none of the notifications received included data on chronic testing," said Dr Jellinek. "Unless the situation is corrected, our review of such notices is going to be based on inadequate data, and we will have to rely on our own studies, such as the use of short-term screening tests, which will mean that the information on which we base our decisions is very uncertain."

Dr Jellinek emphasised that it was not the intent of the FPA to stifle technological innovation through excessive regulation — indeed in many cases regulation had had the effect of stimulating money-saving improvements to production processes. However, in considering the objections of the chemical industry to the agency's activities, it had to be recognised that major breakthroughs in the industry were rare and that most innovation was of a relatively run-of-the-mill variety, which did not necessarily require the same reverential treatment.

However Dr Jellinek said that the aency was considering various ways in which it could "fine-tune" its regulatory efforts, including the possible exemption of certain little used chemical substances from the full requirements of legislative controls, and enabling generic pre-manufacturing notices to be granted on a range of closely-related products.

Earlier in the session, Dr William J McCarville, director of environmental affairs for the Monsanto Company, demanded the separation of scientific decisions from political decisions in the regulatory process — and suggested the creation of a high-level independent scientific panel to answer the scientific needs of all federal agencies that regulate chemical carcinogens. □

United Kingdom

Ex-energy secretary criticises decision-making

FORMER UK Secretary of State for Energy, Mr Tony Benn, has broken the unwritten rules on public exposure of parliamentary procedures by giving an extended interview to Granada television (*World in Action* shown on 7 January) about key decisions taken during his 11 years as a senior Cabinet Minister. According to *World in Action* reporters, Whitehall officials have refused to respond to his criticisms on the grounds that he is breaking a long standing tradition that disputes should be kept behind closed doors.

Mr Benn cites five important issues on which, as the person in charge of Britain's nuclear programme, he was either not informed, misinformed or actively opposed by government bureaucrats.

The 1978 AGR-PWR decision: Benn favoured the British designed advanced gas cooled reactor (AGR) over the US designed pressurised water reactor (PWR) — of the type that failed at Harrisburg — on the grounds of safety. He told *World in Action* that he asked his civil servants to prepare a Cabinet paper in favour of the AGR. Instead, in conjunction with industrialists like Sir Arnold Weinstock of the General Electric Company who had obtained the UK license to build PWRs, they argued that the PWR had better export potential to countries like Iran. His department, he claims, then refused to help his political advisors prepare a brief in line with his views, and the Central Policy Review Staff (think tank) circulated a paper to other ministers directly opposing them. In this case Benn won the argument in favour of AGRs because he "was also making great efforts to see that other ministers knew what this battle was about."

The major Windscale leaks: In 1976, during discussions of expansion of the Windscale nuclear reprocessing facility, Benn heard about the major silo leak from the newspapers. In March last year, he responded to the 30,000 curie-300rem/hr sump leak by calling for a public inquiry in spite of what he describes as "intense political pressure" by the bureaucrats.

The UK-Namibian uranium deal: In 1970, officials in the Department of Energy approved contracts to let the UK nuclear industry obtain uranium from the Rossing mine in Namibia. Namibia was illegally occupied by South Africa and the Labour Government had insisted that it be informed before any contract was signed. The cabinet was not informed of the department's action by what Benn describes as a frequent bureaucratic ploy. Signed contracts are placed in "one or two or perhaps three red boxes a night' without drawing the ministers attention to their importance.

The 1968 theft of 200 tonnes of uranium from Euratom: The theft, from the ship Sheerbourg, bound for Genoa from Antwerp by presumably Israeli agents, was not reported to Benn when he was Energy Secretary on the grounds that Britain was not a member of Euratom.

The Russian Kyshtym nuclear disaster in the 1950s: This was not made public until 1977, although Benn claims that the information was known to the CIA who passed it on to the UK Atomic Energy Authority. The UKAEA did not tell Benn about the accident because, he claims, it feared that the accident "might throw doubt upon the safety of nuclear operations worldwide."

Benn feels that the only remedy to "the state within the state" is to expose the operation of government to public debate.

Joe Schwartz

NEWS IN BRIEF

Japan produces enriched uranium

THE Japanese government announced on 26 December that it had produced enriched uranium from its own factories. Previously, Japan has relied on the US for its supplies of enriched nuclear fuel. A factory in Ningytoge in the western part of the country has produced 300 kg of uranium with a 3.2% concentration of ^{235}U the fissionable isotope of uranium. (^{235}U has a natural abundance of 0.72%). By 1981 the country is expected to produce 50 tonnes of enriched fuel annually. The uranium will be used to fuel Japan's rapidly expanding nuclear programme which envisages the construction of an additional 15 power plants in the next five years, a doubling of present capacity. Enriched uranium at this level can also be used to construct fission bombs.

Evidence on laboratory animals invited

A UK House of Lords select committee which will consider revision of the Cruelty to Animals Act of 1876 has invited written evidence from interested individuals and organisations on current practices in the use of laboratory animals. The committee seeks answers to three questions:

- Is present law and administration for controlling the number and use of laboratory animals unsatisfactory?
- If present law needs admendment, what changes ought to be made?
- Does the proposed House of Lords Laboratory Animals Protection Bill meet the need for reform?

Evidence should be sent before 24 January 1980 to the Clerk, Select Committee on the Laboratory Animals Protection Bill, House of Lords, London SW1 0PW.

Neurochemistry society wins action

THE International Society of Neurochemistry has won its legal action against Pergamon Press to prevent it from continuing to publish a journal with the same name as the society's journal. The dispute arose when the society moved the *Journal of Neurochemistry* from Pergamon to Raven Press earlier this year. After completing a ten year contract with Pergamon, the society sought another publisher because of dissatisfaction with Pergamon's "long publication times" and the "inadequacy of its accounting procedures". Pergamon had insisted that it had the right to publish a journal of the same name and had sent a mailing to subscribers calling for continued subscription to the journal. It had also held back 50 manuscripts whose copyright is held by the society and had refused to release the subscription list. Pergamon now will hand over the subscription list and the unpublished manuscripts and will refrain from publishing any journal under the title "Journal of Neurochemistry". The society now will seek recompense for the 800 non-renewed subscriptions due to the dispute and for its costs in communicating with subscribers about the dispute.

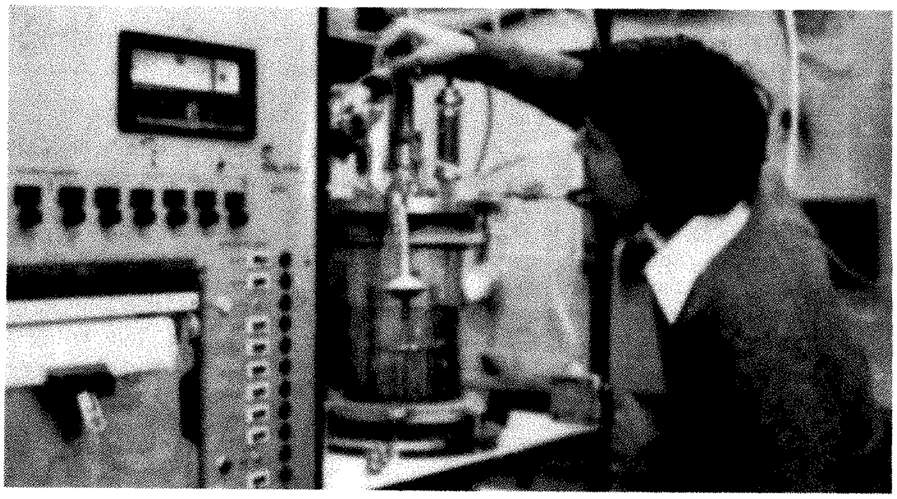
Former Volvo director appointed head of ESA

THE Council of the European Space Agency appointed Mr Erik Quistgaard to the post of Director General at its 19 December meeting. Mr Quistgaard, aged 58 and a Danish national, graduated as a mechanical engineer (MSc) from the Technical University, Copenhagen. He spent three years with the Chrysler Corporation in the US and was General Manager and later director of Volvo in Sweden. After leaving Volvo he became Managing director of Odense-Lindo Stalskibsvaerft A/S, the Danish shipbuilding firm. Quistgaard will replace ESA's present director, Mr Roy Gibson, on 15 May 1980.

0028-0836/80/02121-02$01.00

The biology business

In the first two articles of our special section, we look at the industrial potential of biotechnology and who is likely to exploit it first. **Professor Brian Hartley** of Imperial College, London is optimistic that it will be applied rapidly to many industries — he outlines its promise below. And opposite, **Robert Walgate** compares the efforts of different countries throughout the world



Tuning fermentation conditions before pilot plant trails

The bandwagon begins to roll

WHY should industry and governments think seriously of investing in biotechnology?

First is the tremendous rate of development of the technology itself. Five years ago, even optimists would have predicted that it would be a decade before genetic engineering could be commercially exploited, but this is about to be disproved. The earliest prospect is for new pharmaceuticals made cheaply by fermentation. Human hormones, enzymes or antibodies will replace animal products or create new therapies. Already bacterial fermentation processes for human somatostatin, growth hormone and insulin are patented and there is a world-wide chase for cheap interferon, potentially the wonder-drug of the 80s. Less dramatic, but equally important, is the prospect of new, cheap, safe and effective vaccines. By separating the gene for a viral antigen from the toxic or infective components, this harmless protein could be made cheaply by a microorganism. Such inherently safe products should also reduce expensive toxicity testing. Already progress is reported towards hepatitis B and influenza vaccines, and one can envisage that even measles and the common cold may succumb. Cheap animal vaccines will increase agricultural productivity: the prospects of such vaccines for foot and mouth disease or swine fever now merit consideration of programmes to eradicate these diseases.

Genetic engineering also offers new diagnostic tools to medicine. Enzyme or antibody diagnostic kits for the general practitioner are already a thriving business, and genetic engineering promises novel and cheaper products. Tiny amounts of the DNA or RNA of viruses and microorganisms can now be readily mapped, isolated, sequenced and replicated. Thus new subtypes of viruses can be recognised by their different DNA sequences and "probes" of DNA complementary to these will be invaluable in diagnosis and epidemiology.

The second major factor favouring biotechnology is the dramatic shift in terms of trade, and in public opinion, from fossil fuels to renewable energy resources. Environmental pressures have also forced up the costs of disposal of agricultural and industrial wastes: biotechnology can help by converting these into useful products. The simplest conversion is into microorganisms for animal feed (Single Cell Protein: SCP). For example, a British Petroleum process utilises n-alkanes — a side product of oil refining; a Shell process uses methane, also frequently wasted in oil recovery, and Imperial Chemical Industries grow organisms on methanol obtained from methane. Only the latter is currently judged economic, and then only by virtue of large-scale centralised production.

As petrochemicals become more expensive there are even brighter prospects for biotechnology in production of bulk chemicals. Japan has led the way with a profitable fermentation industry producing amino acids, nucleotides and organic acids, but this relies largely on conventional microbiology, genetics and fermentation feedstocks. It can certainly be challenged by new biotechnology applied to new sources of biomass. Indeed since many microbial products — proteins, polysaccharides, organic acids, for example — could be produced more cheaply than petrochemicals, should we not visualise new biopolymers, biosolvents, and biodetergents?

In this light, enzyme technology will surely take off. Genetic engineers already have ways to persuade microbes to superproduce enzymes of choice and even to secrete them into the medium. Alternatively the superproduced enzymes can be retained within the cell, so that the immobilised cell itself becomes a fixed catalyst. An early example is the ICI process for producing high fructose syrups with immobilised glucose isomerase. This has received the EEC seal of approval by earning a tariff because it competes effectively with sugar beet. Enzymes embedded in membranes can form enzyme electrodes for continuous monitoring of flow processes, and one can foresee membranes that are specifically permeable to a single compound.

Not least is the contribution that biotechnology may make to the world's energy problem. In hot, sticky countries such as Brazil, big schemes are already afoot for producing ethanol from sugar cane or cassava, as a fuel for cars. Moreover big improvements on the current conventional fermentation can be expected; for example, a rapid continuous fermentation by organisms living at high temperatures that would harness the heat of fermentation to distil the ethanol. Thus as the price of oil continues to soar, the Brazilian adventure seems to be far from a risk. Indeed, Western developed countries are beginning to examine their own resources of biomass for energy; industrial and agricultural wastes are an obvious target and, just around the corner are processes for converting cellulose into liquid or gaseous fuels. Then a really balanced alternative to our oil-based economy will have arrived. ☐

0028-0836/80/02122-02$01.00

Who's ahead, who's behind?

Between 1967 and 1971, when immobilised enzymes were emerging as the first wave of the new biobusiness, 30% of world biotechnological patents originated in one country: the UK. But of the patents delivered since 1977, 124 originated in Japan, 39 in the US, 9 in the USSR, 8 in West Germany, 7 in France, one in Denmark, and just one in the UK.

Armed with this rather depressing information for Europe, the European Commission requested two biologists — Dr Artur Rörsch of Leiden State University, The Netherlands, and Dr Daniel Thomas of the University of Compiegne, France, to produce reports* on the status and potential of genetic manipulations in applied biology, and of the production and exploitation of biological catalysts.

Meanwhile in France, Professor François Gros, Director of the Institut Pasteur, Professor François Jacob, Nobel laureate and also at the Institut Pasteur, and Professor Peirre Royer of the Delegation Generale pour la Recherche Scientifique et Technique were producing a report* on biotechnology for the President of the Republic, Giscard d'Estaing.

All these reports carry reviews of the state of the art in biotechnology around the world; together they provide a worldwide picture.

Japanese domination

Japan has taken an incontestable lead in biotechnology. The company Tanabe Seiyaku is credited with the first application of immobilised enzymes in 1969. It used aminoacylase carried on DEAE-Sephadex for the continuous production of L-amino acids from acyl-DL-amino acids, reducing overall operating costs compared with a free-enzyme, batch process by 40%.

Now five companies are in active production, in processes involving four different fixed enzymes — aminoacylase, aspartase, glucose isomerase, and penicillin acylase — and three fixed cells — *Escherichia coli*, using its aspartase metabolism, *Brevibacterium ammoniagenes* (fumarase) , and *Streptomyces* sp. (glucose isomerase). The Tanabe Seiyaku company has also developed processes involving fixed cells of *Pseudomonas putida* (L-arginine deiminase), *Achromobacter liquidum* (L-histidine ammonialyse), and *E. coli* (penicillin amidase). Many biotechnologists believe that the fixation of cells and cell organelles is the way forward for enzyme technology, and perhaps also for the use of genetically engineered microorganisms.

Japan's industrial interest has to some extent been stimulated by the numerous traditional fermented food industries, producing miso and shoyu and the drink sake through the *Aspergillus oryzae* amylases. The average consumption of miso is apparently 24 gm/person/day, and the producers have not been slow to attempt to capitalise on the new biology. The fermentation industry represents some 2-3% of Japan's GNP.

Outside industry, government has also taken a strong interest, particularly through the Office for Life Science Promotion headed by Professor A Wada. This office has set up a systematic programme for the research and development of enzyme technology, and has made a detailed analysis of its possible impacts on industry and society. "The association between a well-defined plan and the Japanese potential is unique in the world" writes Thomas in his report.*

The recently published French report* suggests that Japan has chosen to make an all-out effort on biotechnology because of the potentially high added value the technology can give to imported raw materials. In a country as dependent on imports as Japan this is an important consideration.

Furthermore Japan already enjoys "a very high reputation as one of the principal world producers of antibiotics" through fermentation, and the country intends to maintain this position through its research. "It is clear that in Japan there is no official or conceptual division between basic and applied research; there is a continuous exchange of skills and services between universities and industry".

However there is a feeling that Japan is not as advanced as some other countries in fundamental biology, so international competition particularly through genetically engineered organisms is not closed.

US catches up

America is the second most advanced country in this field, judging by patents and production. "The patent list shows that industrial interest in enzyme technology is significant, but so far the only large scale application is the production of fructose syrups by several companies" writes Thomas.*

But he forecasts an "explosion" in applications which should flow from the Research Applied to National Needs programme of the National Science Foundation. A strong interdisciplinary team at the MIT has been focusing on the total enzyme synthesis of gramicidin, a cyclic decapeptide antibiotic. This problem tackles head on the major obstacle to application of synthetic as opposed to degradative pathways: the cost-effective provision and regeneration of small cofactor molecules such as ATP and NADH.

The country that finds a practical solution to this problem, and patents it, will find itself at a major advantage compared with others; but there is some scepticism about whether extra-cellular systems will ever be successful.

Some eight cell species have been successfully immobilised in the laboratory in the US: *Streptomyces venezuelae* and *Bacillus* sp (for producing fructose), *Saccharomyces cerevisiae* (invert sugar), *E. coli* (fumaric acid), *Nocadia erythropolis* (Δ^4-cholesterone), *Corynebacterium simplex* (prednisolone), *Serratia marcescens* (2-keto gluconic acid), and *Corynebacterium lilium* (glutamic acid).

Moreover the US is well-advanced in applied recombinant DNA techniques — the production of somatostatin for research purposes being promised shortly, with insulin also on the way; and it has a very strong base in fundamental biology. Research and development organisations based on venture capital are very active (see *Nature* **278**, 494; 1979), and at least one (Genentech) is active in recruiting scientists outside the US, particularly in Europe.

Soviet secrecy

Soviet commitment to biotechnology, indeed to all aspects of molecular biology, began officially with the decree of 21 May, 1974, which set Soviet science the task of "accelerating the development of molecular biology and molecular genetics" and the "wide use of their achievements in agriculture, medicine and industry". Considerable human and financial resources were committed to closing the

**"Genetic manipulations in applied biology" by A Rörsch, catalogue number CD-NI-78-001-EN-C; "Production of biological catalysts, stabilization and exploitation" by D Thomas, CD-NI-78—002-EN-C, available from offices for official publications of the European Communities; and "Sciences de la vie et Societe" by François Gros, François Jacob, and Pierre Royer, available from La Documentation francaise.*

gap left by Lysenkoism.

Partly as a result of Lysenkoism, Soviet "applied" genetics has a strong commitment to radiation-produced mutations. However, several groups throughout the USSR are known to be working on applied genetic engineering, and there have been several hints that the industrial breakthrough point for "certain medical products" made in this way will be reached "in the nearest future".

Most socialist countries, however, are somewhat secretive as to detail. One exception is Hungary, with its international biology centre at Szeged (built largely by UNDP funds). Work at Szeged, however, is still largely at the stage of establishing techniques and principles. One team, researching on nitrogen fixation, recently started work on establishing a genetic map for *Rhizobium* and studying the genetic structure of chemically produced mutants.

In Poland, however, the Institute of Biochemistry and Biophysics of the Academy of Sciences would put the breakthrough point for nitrogen fixation by "agricultural plants" at the order of 20 years ahead. According to interviews which specialists from the institute recently gave the prestigious weekly *Polityka,* they would put on the same time-scale the modification of cereal genes so that the grain proteins would provide the whole range of aminoacids needed for human nutrition. In the "near future", on the other hand, they expect the commercial production of hormones (unspecified), vaccines and special microorganisms designed to clean up pollution. **Vera Rich**

Germany leads in Europe

A major initiative in the European Economic community is discussed opposite — but, in outline, Europe starts well behind Japan and the US in the application of modern biology. Within Europe, West Germany is generally reckoned to be in the lead: government spending on the basic problems of biotechnology is about ten times that in France or the UK, for example. Altogether, between 1972-78, the federal government invested £35 million in biotechnological R&D.

One of the highlights of the German effort is the Gesellschaft für Biotechnologische für Forschung mbH at Braunschweig near Hannover, with an annual budget in 1977 of some £5 million. It was created in the early days of biotechnology — the mid sixties — by the Volkswagen foundation, but was later taken over by government. It has a staff of some 80 researchers and support staff, but has been criticised by some for being insufficiently productive. A new director, Professor Kieslich, has recently been appointed.

The science ministry (Bundesministerium für Forschung und Technology) also plays an active part in funding and planning biotechnological research and development in university and industry; its programme is the envy of biotechnologists in other European countries. So far Germany's greatest efforts lie in its government based research programme.

Italy has a fairly advanced programme, particularly through the activities of the firm SNAM-Progetti, which operates a large laboratory devoted to biotechnology at Monterotondo, near Rome; and Sweden can boast ground-breaking work at the Universities of Lund and Upsalla. In Switzerland Nestlé "is devoting a big effort" (Thomas). (UK and French programmes discussed opposite). ☐

The origins of biotechnology

THE most ancient biotechnological art is fermentation — in the raising of dough, the brewing of alcohol, and the production of tea, coffee, and cocoa (each of which requires a fermentation step). But the new wave of biotechnology rests on two main techniques: genetic manipulation and enzyme (or cell and cell organelle) immobilisation.

Genetic manipulation is used by the biotechnologist to enhance the natural genetic repertoire of a microorganism. The aim is usually to donate to the microorganism a gene for an enzyme or a hormone in such a way that the product of that gene is thenceforth synethesised by the microorganism. The successful development of genetic manipulation has rested upon the discovery of new enzymes and the improvement of old techniques by molecular biologists and microbiologists.

Crucial to the success has been the development of vectors for carrying foreign genes into microorganisms. Also of great importance has been the acceleration of DNA sequencing technology.

The real cornerstone of genetic manipulation, however, has been the discovery of enzymes that cut DNA at specific sites (restriction enzymes), seal the cuts up (ligase) and copy DNA from messenger RNA (reverse transcriptase). The first two of these are needed for the insertion of foreign genes into the DNA of the vector. Reverse transcriptase has become particularly important in the last two years since the revelation that the genes of higher organisms are 'split' (the coding DNA being interrupted by non-coding segments). In sharp contrast, bacteria do not have split genes and cannot decode split genes that are transferred to them. Therefore it is necessary to transfer an unsplit equivalent of the gene, which is precisely what reverse transcriptase produces from messenger RNA. Alternatively, due to recent advances in the technique of DNA synthesis, it is also possible to make purely synthetic genes at least for small peptide hormones.

The use of enzymes is an older technique, applied in a number of industries from baking to detergents. But purified enzymes are soluble molecules and it is therefore not easy to separate them from the product of their labour. Furthermore it is difficult to recycle the enzyme. These difficulties have led to the development, in the late 1960s, of immobilised enzymes. The enzyme is bound chemically to a solid matrix or entrapped in a small-pore gel.

Immobilised enzymes have been successfully applied, for example, to the production of semi-synthetic penicillins, to the large-scale production of fructose from maize, and to a simple assay for blood cholesterol.

Immobilised cells or organelles have potential advantages when the stabilisation of an enzyme is difficult, or when a coenzyme or sequence of enzymes is required for synthesis.

Biotechnology may be dominated by microbial and enzyme technology, but it is certainly not synonymous with them. Both animal and plant cells have their place in the armoury of the catholic biotechnologist. Successful exploitation of animal cells has been achieved, for example, by Wellcome Research Laboratories in the production of interferon from virus-stimulated lymphoblastiod cells.

A completely distinct exploitation of animal cells lies behind the commercial production of high grade antibodies for research, diagnostic and clinical use (for example for tissue typing prior to transplantation). The key to that is the hybridoma cell, an 'invention' of five years ago. Natural antibody-secreting cells neither survive long enough in culture nor produce pure enough antibodies to be a commercial source of antibody. But a hybridoma cell, the result of fusing an antibody-producing cell with a tumour cell, grows and divides continually. And all the cells from the original hybridoma secrete the same, pure antibody.

Work is also going ahead in many countries on the problem of nitrogen fixation — attempting to extend the range of associations of the nodule-forming, nitrogen-fixing, bacterium *Rhizobium* to plants other than the *Leguminosae* (particularly cereals), or to transfer the nitrogen fixing genes to plants — a distant prospect, given the extreme oxygen sensitivity of the pathway. There is also the distant prospect, through genetic manipulation, of a new source of controlled genetic variability in plants to produce new high yielding or resistant varieties.

Peter Newmark

0028-0836/80/02124-01$01.00

Brussels asked to spend £16m on biotechnology

Today, the EEC's thirteen Commissioners are being presented with a proposal for a five year (1981-85) community programme for research and development in 'biomolecular engineering'. Here, **Robert Walgate** outlines the proposal and the rationale behind it. Over the page, he summarises a report on biotechnical safety prepared for the Commission.

THE proposal being put before the Commission has been originated by a small team of officials in the research directorate of the Commission; the officials are themselves active in biological research, but their proposal is based on a wide range of advice from experts, government officials, and industry received over the last two or three years. It will only become official if first, it is approved by the Commission and second, it is accepted by member governments through the Council of Ministers. If all went smoothly, this process could be complete by the end of April.

The programme would be an 'indirect action', whereby the Community budget would contribute half the costs of research projects, and contracting parties the other half. The proposed Community contribution is 23.5 million European Units of Account (about £16 million) divided over nine countries and five years — crudely some £300,000 per year per country, although the allocation will be strictly according to the quality and suitability of individual applications. The amount is small compared to Germany's national effort, but would in the UK for example, match the Science Research Council's present expenditure — so the proposal is far from negligible. European industry has recommended its speedy implementation.

There would be six projects in the programme. They are designed in part to tackle basic technical obstacles to the development of biotechnology, and in part to suit particular European problems. The programme is outlined below.

French views

Professor Daniel Thomas, enzyme technologist at the new University of Compiègne, near Paris, is naturally in favour of an EEC effort: he wrote the report which forms the basis of the first and second projects. He feels one of the main advantages of an EEC action will be that it promotes cooperation. 'In Europe we have better contact with the US than we do with each other" he says. Cooperation might be difficult on development questions, but on basic research a coordinated programme would be "very helpful".

"There are some 4000 PhD biotechnologists in Japan; in France we have only about 200. We need a critical mass in Europe to compete with Japan and the US."

Fundamental biology is of a very high quality in Europe, Thomas believes, and though industry is at a low level, it is good enough to succeed "if there is a big effort". But Europe cannot hope to "reproduce Japan". The first ten companies in biotechnology in Japan have grown out of the food industry, which took an early enlightened attitude to the new biology.

In America, dedicated contract research organisations such as Biogen, Cetus, and Genentech were thought to be the answer "but it would be better in Europe to arrange loose links between academic institutions and industry". This is one of the objectives of the proposed EEC programme.

A big leap forward in biotechnology requires "both high level work and classical fermentation chemistry" says Thomas. The effective application of genetic manipulation is, he believes, a long term goal; "in the short and middle term we must look at enzymes and fermentation". The fundamental bottlenecks in enzyme technology could be solved — scientifically at least — within five years, he believes.

France has been slow to recognise the importance of biotechnology. "Before the report to the President (see footnote p123) the very words 'biotechnology' and 'enzyme technology' did not exist in

The proposed EEC programme

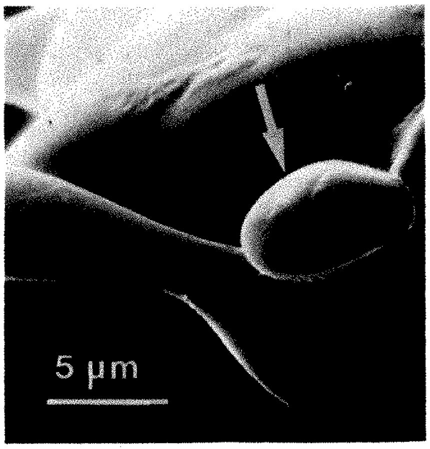
In bare outline, the programme consists of:

First project: enzyme technology, involving

- reactor kinetics and geometries for multi-enzyme reactions
- immobilisation of multi-enzymes and co-factor regeneration
- stabilisation of lipid-requiring enzymes and development of reactors for reactions at a hydro-organic interface
- stabilisation of sub-cellular organelles such as mitochondria, chloroplasts and peroxisomes and of membrane-bound enzymatic complexes in the form of microsomes, thylakoids, and inner mitochondrial and plasma membranes; and of intact eukaryotic plant and yeast cells.

Second project: development of methods for industrial and human detoxification, involving

- bio-compatible insoluble matrices
- targeted carriers, with specific tropisms, for administering medical enzyme products



Immobilised lettuce chloroplast: the EEC's energy programme is already supporting research on the production of hydrogen from immobilised chloroplasts associated to bacteria hydrogenase

- enzymatic detoxification of poisons.

Third project: transfer of genes to *E. coli*, the yeast *Saccharomyces cerevisiae*, and 'other suitable organisms', involving:

- overcoming expression barriers
- construction of 'synthetic genes'
- development of mutational tools to produce, for example, harmless vaccines or stabilised enzymes
- modification of enzymes to inhibit their degradation in a foreign environment
- development of 'libraries' of expressed genetic information and rapid screening techniques for their identification

Fourth project: development of cloning vehicles in organisms which are likely to be of greater importance to industry than *E. coli*, such as the bacteria *Actinomycetes*, *Pseudomonas*, and *Bacilli*, the fungi *Penicillium*, and algae, using plasmids, viruses, and mitochondrial DNA; and in plants using potential vehicles such as *Agrobacterium* plasmids, plant DNA viruses chloroplasts and mitochondria.

Fifth project: stability, regulation, and expression of transferred genes, including the regeneration *in vitro* of plant cells

Sixth project: improved methods for detecting contamination in fermented strains.

In each of the six projects, some three to 12 research groups would participate; each group would consist of, on average, three researchers, two technicians, one laboratory helper, and 'secretarial assistance'.

0028-0836/80/02125-02$01.00

France" says Thomas. Funds for his work at Compiègne came in small amounts from a dozen different sources. But now, after saturation coverage for two weeks on television and the newspapers "everyone was trying to do it".

But there are dangers in this sudden enthusiasm, he feels: biotechnology is not the panacea the media have taken it to be.

English disease

Looking over the water to England, Thomas is "very surprised" that the University College, London, group of Malcolm Lilly and Peter Dunhill " — the first in the field — get so little money".

Lilly, it should be said, does not complain at the size of his share of the small British cake in biotechnology, but is unhappy with the size of his group: "two more lectureships and an administrator would change the picture overnight" he told *Nature*.

Lilly's group is unique in the UK in combining chemical engineers and biologists — essential for good biotechnical work, Lilly believes. Biologists must feed the engineers with science, and the engineers feed the biologists with problems; and "ideas are transferred from person to person". Technology transfer is, Lilly feels, "bloody hard work!".

He spends about one day a week talking with industrialists: "one desperately wants good industrial/academic liaison".

There are two categories of biotechnologist in England: the recognised specialists, and people in associated fields who are attempting to find application for their work. "These people need guidance" says Lilly.

There are very many plausible applications, "but we have learned to be very selective in what we offer industry". Much work needs to be done between idea and application, and an ill-thought out idea will ultimately fail.

The number and age of biotechnologists is a central problem in the UK, he believes. "Most specialists are in their forties, and isolated in biochemical or engineering departments" where they have risked becoming black sheep. Very few departments have appointed younger people to follow them through. "The reason we've done better than others in the UK is that there were always two of us. We could talk to each other."

Lilly's group now consists of three full-time researchers, plus 20 technical staff and research students. "If I had two vacant lectureships I could fill them tomorrow" he says.

The potential economic productivity of such an investment is high, he believes. In the early days of enzyme technology in the UK some £500,000 was spent on research grants. The result was industrial immobilised enzyme processes, of which the biggest was fructose production, then the deacylation of benzyl penicillin.

For the future the main problem is handling co-factors in biosynthetic pathways. But here one should not distinguish enzyme and cell immobilisation: for example with glucose isomerase for fructose production some firms use cells, others the isolated enzyme. Where co-factors are required, whole cells have the edge. Fermentation also will remain important, particularly for methane production and waste treatment.

The key to industrial success, Lilly believes, will be to look for products of high added value, insulated from volatile market forces. For instance, the fermentation of sugar to produce industrial alcohol "is at the whim of the weather", which affects sugar prices; and single cell protein is similarly affected by the price of conventionally grown soya protein with which it competes as fodder.

Professor Lilly may take heart from the signs that the UK is about to make a second effort in biotechnology: a Royal Society committee on biotechnology is about to report, there are moves afoot to set up a British version of the American Biogen company, and the National Research Development Corporation is reportedly poised to make an increased investment — more in proportion to its revenue from biological patents, which greatly exceed its revenue from physical technologies.

And at the Science Research Council, which currently spends some £300,000 a year on biotechnology, a joint panel is shortly to be set up involving industrialists and academics; the panel will recommend by the Autumn a coordinated programme in biotechnology. According to Dr Geoffrey Potter, chief administrator of the SRC's Engineering Board, one of the main objectives will be to train new biotechnologists, or to help existing biologists shift towards technology. □

How safe will biobusiness be?

"THE cow," write two biologists invited by the European Commission to produce a report on the hazards of biotechnology, "is a live, mobile, self-reproducing and edible fermenter." To digest grass and produce milk it employs a complex and varying mixed culture of anaerobic microorganisms in its rumen; some of these have not even been characterised.

"The cow can become infected with pathogens, including foot and mouth disease virus, *Brucella abortus,* and *Mycobacterium tuberculosis*, which can damage or destroy the fermenter and infect the product. In the past it has been a major source of human brucellosis and tuberculosis.

"A singular disadvantage of this fermenter system is that it can only be scaled up by increasing the number of units; moreover its productivity, in terms of protein production, is only 0.0025 compared with that of an equal weight of microorganisms growing in an industrial fermenter."

Conjectural hazards of supposedly 'unnatural' techniques are not of happy memory for molecular biologists who alerted the world to what are now widely accepted as the largely imaginary risks of research using recombinant DNA. But painful though it may be, the questions must be re-thought if industries based on these and other new biological techniques are to be set up.

The scale of industrial processes, using 1000 to 30,000 litre fermenters, is vastly greater, and process control is more difficult. Also there is an economic disincentive to using severely disabled strains, and little attention has been paid to the dangers of the use of plant pathogens.

These and other issues have been raised in the report quoted above by Drs K. Sargeant and C.G.T. Evans of the Microbiological Research Establishment, Porton, UK. They conclude that:

- The special hazards of biobusiness rest only in the potential of some microorganisms to infect higher species and cause disease.
- "With the exception of a few that affect plants and insects, it is very unlikely that dangerous pathogens will be used on a large industrial scale."
- Research is needed on the long-range airborne transmission of, especially, plant pathogens.
- "For diagnosis, research and vaccine production some highly dangerous human and animal pathogens must continue to be grown on a small scale. A list of such organisms should be drawn up, and their handling, except under licence, should be forbidden. . ."
- "The chemistry of a proved and licensed fermentation process can alter in response to genotypic and phenotypic changes in the culture. These can be difficult to detect, especially in long-term continuous processes."
- Hence, research is needed on the rapid detection of small numbers of contaminant microorganisms within large populations; and on the mechanisms of, and potential for, phenotypic change.

On regulation of the industry in Europe, Sargeant and Evans argue that biotechnology will be "too diverse to be encompassed by a single set of regulations". Rather, they recommend that "regulations should be worked out by associations of manufacturers of product types in conjunction with governments, and harmonised within the EEC. This is already happening for food enzymes and single cell protein".

0028-0836/80/02126-02$01.00

In their review of hazards, Sargeant and Evans keep the problem firmly in perspective. ''Pathogenic microorganisms are a normal feature of our environment, held in check by Public Health measures and an informed food technology.'' The dangers of large-scale biotechnology must be seen against this background.

The main new features are scale of production, the large numbers of workers exposed to the organisms and their products, and the possibility of inadvertent release affecting the environment.

'Avirulent strains' may not be what they seem. ''Avirulence is a matter of degree, related to dose, portal of entry, and resistance of the host. Although so far unknown, the enhancement of virulence by phage transduction is a possibility. . . that should not be entirely ignored.''

The production of diphtheria toxin, the authors point out, is associated with the presence within *Corynebacterium diphtheriae* of a bacteriophage.

Further, the contents of the fermenter may not be what they were thought to be. They may become contaminated with foreign organisms (unless the fermenters are well closed), or there may be phenotypic variation.

One of the main ways the latter could occur is inadvertent change of the growth limiting nutrient, perhaps by failure of the supply line of a medium component. ''Cell walls of rapidly growing phosphate-limited *Klebsiella aerogenes* NCTC 418 are only slightly toxic to mice whereas similar, but carbon limited cell walls are highly toxic.''

The change from batch to continuous culture can also change the character of an organism: batch grown cells of the live vaccine strain of *Francisella turlarensis* are much more toxic to mice than the continuous grown cells, although the protection is equal.

Change of temperature can also be important. At 15°C and 45°C the aflatoxins are produced by *Aspergillus flavus* in only trace amounts on groundnuts; at 35°C, under otherwise identical conditions, 40mg/kg are produced. And change of *p*H through failure of the control system — ''a not unknown occurrence'' — can also cause major phenotypic changes. Change of trace elements in the feedstocks may also stimulate or inhibit the production of particular metabolites.

Sargeant and Evans illustrate the danger with ''an entirely hypothetical, but easily credible, example''.

''Until 1960, *A. flavus* was regarded as a harmless mould closely related to the *A. oryzae* strains used in Japan for making miso, shoyu and sake. It would not have been unreasonable to think that a pure culture of *A. flavus* could be eaten with impunity.

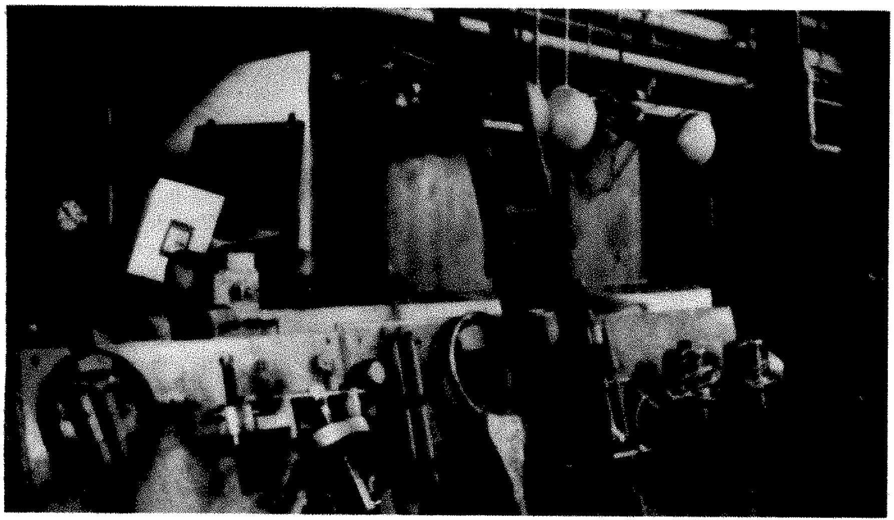
''In 1960, major outbreaks of a 'new' disease among turkey poults and ducklings — turkey X disease — were encountered in the UK. The cause was traced to a new group of toxins, now known as the aflatoxins, which were generated on contaminated groundnuts by some strains of *A. flavus*.

''It has since been shown that aflatoxins can cause serious disease in many animals, including man; epidemiological studies suggest that they are a major cause of human liver cancer in some parts of the world.

''*A. oryzae* was being developed in 1960 as a source of amylases for bread making, but it could have seemed reasonable to develop *A. flavus* instead. Alternatively a potentially toxigenic strain of *A. oryzae* could have been used, and, by chance, growth conditions that did not allow aflatoxin production could have been chosen.

''After careful testing, the product could have been declared safe. Subsequently, a small inadvertent change in the growth conditions could have led to the production of very heat stable aflatoxins and to their inclusion in our daily bread.''

However, those primarily at risk are the workers, subjected to ''the dense aerosols of microorganisms which, in the absence of suitable precautions, will be released into the factory atmosphere during recovery of the products of fermentation by centrifugation, spray, or flash drying, packaging and handling of the product, and release of the culture supernatant.''



Hard-headed about safety: inside a biotechnical laboratory in London

Outside the factory residents are no more likely to be at risk than those near a mechanically aerated sewage works ''with its potential population of human pathogens''.

The products of enzyme-based factories — such as the high fructose syrups used in soft drinks — may be contaminated with enzyme, and the effect of long-term low-level exposure is unknown. But the non-biological contaminants of soft drinks — such as sugar and phosphoric acid — may themselves have greater deleterious effects.

Man's environment could be affected by the discharge of nutrients, increasing microbial, algal and plant growth, but this problem is not exclusive to biotechnology.

The discharge of live organisms might have ecological effects, but since the strains will be unnaturally specialised their release would be ''tantamount to abandoning an over-bred and pampered European lap-dog to its fate in Siberia. We have been authoritatively informed that when, some years ago, the contents of a very large antibiotic fermenter were inadvertently discharged into the sea, no trace of the organism could be detected the next day, despite a very thorough, widespread, and anxious search.''

More dangerous might be the continuous low-level discharge of antibiotic, creating ideal conditions for the selection of resistant organisms. If contained on a plasmid that information could be transmitted throughout the microbial world. However, the widespread use of antibiotics in animal feedstuffs is a greater danger, the authors suggest.

The use of plant pathogens in increasing: ''the 400-litre production scale of the anti-leukaemia enzyme asparaginase from *Erwinia chrysanthemi* — pathogenic for chrysanthemums — has been completely overshadowed by that of xanthan gum from *Xanthomonas campestris* — pathogenic for brassicas.''

Most serious is the potential airborne dissemination of such organisms to countries in which they are not indigenous; ''and their aerosol survival and infectivity have been attributed to the production of the very gum for which they are grown''.

Finally there is the danger of the establishment of new genotypes during continuous cultivation, where organisms are maintained through many thousands of generations.

''If a contaminant arose which was able to maintain itself...then no guarantee concerning either the safety of the process or the culture could be given.

''The situation is in this respect fundamentally different from farming with plants and animals, where much more precise control of the genotype is possible — because one generation is cultivated at a time and alterations in the genotype are...much more obvious.''

Robert Walgate

Patenting living organisms — how to beat the bug-rustlers

Attempts to patent 'live' biological processes have raised wide debate about the legal and philosophical implications. But patent protection may prove less attractive than a strategy of closely-guarded research and swift commercialisation. **David Dickson** reports from Washington

FIVE days before Christmas, the Upjohn Company dropped a firecracker from one of the most keenly-awaited decisions facing the Supreme Court — whether patents can be granted for living organisms.

Officials of the pharmaceutical company say they have withdrawn a patent application for a strain of bacteria capable of producing the antibiotic lyncomycin, first filed in 1975, to focus the court's attention on a second application involved in the same decision, filed by scientists with the General Electric Company.

Unlike the Upjohn bacterium, which is essentially the refinement of a strain discovered in nature, the GEC case involves a strain of bacteria of the *Pseudomonas* genus genetically altered to maximise its effectiveness in degrading oil spills — a manipulation which, although it did not make use of the now-familiar gene-splicing techniques, is still considered "genetic engineering".

Yet the Upjohn patent application had already been approved by the Court of Customs and Patent Appeals, overturning an earlier rejection by the Patent and Trademark Office. The company's surprise withdrawal is therefore a further indication of the extent to which the recent rapid marriage between modern biology and industrial production has caught traditional legal machinery unawares.

'The line between life and non-life is so fine as to baffle even the experts'

Furthermore, while lawyers and philosophers debate the subtleties raised by the private ownership of living matter, others claim that patent protection may be only marginally relevant. Greater profits can be found in a combination of closely-guarded research and rapid commercialisation of the results, closer to the strategy of advanced electronics firms than the conventional ways of doing business in the chemical or pharmaceutical industry.

Turning scientific knowledge into a commodity has produced relatively few problems of definition in the physical sciences. Biology has proved less amenable. The Appeals Court, in granting the two patent applications, found little difficulty in classifying microorganisms as "industrial tools", or in concluding that "life is largely chemistry" — but critics see it as the thin end of a wedge that opens the door to private ownership and control of the evolutionary process itself.

Congress has already faced this dilemma. In the 1920s, when plant breeders began pressing for patent protection for new strains of seeds, it decided that plants were not covered, and in 1930 it passed the Plant Protection Act broadening the definition of patentable matter to include certain varieties of plants.

The argument of those now seeking to patent microorganisms is that, as previously the case with plant biochemistry, modern biology has so blurred the distinction between animate and inanimate matter as to make the concept of life — in the strict legal sense — almost irrelevant.

"Surely where the line between life and non-life is so fine as to baffle even the experts in the art and at times cannot be drawn with conviction, compositions of matter or manufactures near the periphery cannot conveniently be deemed patentable or unpatentable on so ephemeral a ground," according to an *Amicus Curiae* (friend of the court) brief filed by the University of California at Berkeley.

According to such arguments, there is nothing special about life that makes it inherently unpatentable. "We do not see any sound reason for making the distinction between the living and the dead," wrote Judge Rich in giving the Appeals Court's reasons for approving the patent application.

According to the court, it is precisely because organisms are alive that they can be useful. "We see no sound reason to refuse patent protection to the microorganisms themselves, or to pure microorganism cultures — the tools used by chemical manufacturers in the same way as they use chemical elements, compounds and compositions — when they are new and unobvious."

The Solicitor General, in appealing the decision to the Supreme Court, has sidestepped the philosophical issues to argue that, whether or not living forms should be patentable, they are not covered by present legislation; that Congress's previous introduction of new laws covering plants was a recognition of this fact; and that given the wide social and ethical implications of the current cases, the issues should be resolved by Congress rather than the courts.

If the Supreme Court decides to pass the buck back to Congress — and this would be consistent with other recent rulings — the stage will be set for a further round of public debate on the social consequences of genetic engineering. And in this case, the focus will not be on their potential hazards, but who is entitled to benefit financially from their use.

Opposing the argument that the creation of substances by live processes should be treated no differently from ordinary mechanical production processes, critics say that sufficient protection for useful techniques can still be obtained without necessarily giving away title to complete organisms.

Dr Burke Zimmerman, previously a congressional staff member closely involved with attempts to legislate recombinant DNA research and now with the National Institutes of Health, believes that a law permitting the patenting of living organisms would lead to "irresoluble logical inconsistencies". "To patent a living organism that is to be used only in a very specific way is *not* equivalent to patenting the particular use one may wish to put it to," says Dr Zimmerman. "Thus the classical justification for patenting an invention or even a composition of matter breaks down when applied to a living organism."

Others go further to argue the moral case as part of a general critique of the undesirability of genetic engineering. It is strongly put by the People's Business Commission, a Washington-based research organisation. "To justify patenting living organisms, those who seek such patents must argue that life has no 'vital' or sacred property; that all of life's properties can ultimately be reduced to the 'physico-chemical,'" says the PBC in a brief filed in support of the Justice Department's appeal to the Supreme Court. Furthermore, says the PBC, any such decision could set a dangerous precedent. "If patents are granted on

0028-0836/80/02128-02$01.00

microorganisms there is no scientific or legally viable definition of 'life' that will preclude extending patents to higher forms of life," the group argues.

Yet whether the issue is settled by the Supreme Court or by Congress, many now argue that the patent system may be incapable of providing adequate protection. Although patents provide 17 years protected use, they require in return full publication of the procedures used as a form of public education. Many fear su disclosure could provide important clu potential competitors who, w directly infringing patent righ n quickly come up with riv the

Others argue that althoug ch. may be granted by an entary) prove difficult to de ow rely general ubiquity of in relative marketing

fors to vary across the those who feel that the e most important thing we ers who feel it is almost ant", says Nelson Schneider of investment analysts E.F. Hutton, a close observer of biotechnology developments. "The problems are more in the area of fears about what someone else is going to do, rather than seeing anyone else do it. I am aware of no-one who, if they made a really great breakthrough in the field, would immediately file a patent application — they would prefer to sit on it."

'The classical justification breaks down when applied to a living organism'

That market dominance can be as effective as patent protection has already been illustrated by the pharmaceutical company Eli Lilly. Last year Lilly, which currently has about 85% of the domestic insulin market, agreed with the Federal Trade Commission to make both supplies of animal pancreas and the appropriate refining technology available to anyone interested — yet such is the company's prominent position in the market, and the economies of scale it is therefore able to effect, that other companies have been reluctant to take up the challenge.

Eli Lilly is now engaged with Genentech in developing the artificial production of human insulin, with hopes that it could be on the market by the end of the year. And this speed is dictated partly by the need to

'. . . a philosophical reductionism already responsible for the destruction of natural ecosystems and alienation of humanity from nature'

tial competitors who may head off working o synthetic insulin also ion.

preary emphasis on marketing may be more necessary to maximise returns another new biotechnology which is xpanding raidly, the production of monoclonal antibodies with highly specific characteristics from hybrid cell lines. By fusing a mouse spleen cell and a rapidly-reproducing tumour cell, and selecting out those resultant cells producing antibodies with particular desired characteristics, Dr Cesar Milstein and Dr George Kohler at Cambridge, England, have opened the way to a reliable method for the general production of antibodies.

But even more than with genetically-manipulated microorganisms, the information contained in a patent application on a hybrid cell-line describing its usefulness may provide an idea of how the same result could be achieved by a slighly different route. "Even if it does turn out to be possible to patent cell lines, we are not sure that it would be worthwhile," says Dr Howard Birndorf, vice-president of Hybritech, a west coast firm set up with the same source of venture capital as Cetus and Genentech. It is already marketing monoclonal antibodies to the hepatitis B surface antigen, and promises many more. "Rather than going for patent protection, we have chosen to develop techniques and processes in-house, staying more under trade-secret type protection," says Dr Birndorf.

Once a technique is perfected, the strategy is to market the product as quickly and as widely as possible, attempting to build a quick lead over potential rivals. "In immunodiagnostics the person who is first traditionally gets the largest share of the market," says Dr Birndorf. And he compares the hybridoma field to the semiconductor industry, where it is the company that can raise the number of useable silicon chips from two to 30 in a hundred that wins out.

But while secretive research and aggressive marketing may suit the style of the small, venture-capital-based firms, they fit less easily into the traditional *modus operandi* of biological research.

Many biologists, caught up for the first time in what may turn out to be highly lucrative research, but uncertain of procedures and frightened of giving anything away unwittingly, have become confused about what to do. Others are accused of violating the spirit of the research community.

"Scientific meetings in this field used to be free and open," says one observer. "Now everyone sits on their hands in a corner, not talking to anyone else. There is a fear of what you may giving away — and how long it may take before you know what you have done."

Mr Neils Reimers, head of the Technology Licensing Office at Stanford University, claims this is as much the fault of the rush to publication as of the demands of the patent system. But he accepts that arranging the commercial exploitation of biological advances in ways mutally beneficial to the public at large, private corporations and the university scientists who carried out the original work had raised problems.

Even with the recombinant DNA techniques, once a patent has been granted, it may prove difficult to enforce. Stanford, for example, has already applied for a share of the patent rights to the original gene-splicing techniques developed by Dr Stanley Cohen and Dr Herbert Boyer. And if this is granted, various companies have suggested that they may challenge the patent if they feel the university is demanding too high a licence fee.

Such difficulties in enforcing patent claims mean that, despite the potentially lucrative discoveries now emerging from biology laboratories, universities may not find them the gold-mine that some have speculated. But there are already moves in Washington to assist universities if they do come up with a winner.

In a package of recommendations issued in November, and designed to stimulate industrial innovation, President Carter proposed among other things a revision of the patent law making it easier for universities and small businesses to retain the patent rights on discoveries resulting from federally-sponsored research.

This will be done through a system of what are known as Institutional Patent Agreements. To qualify for an IPA, a university must demonstrate an ability to transfer research results to the private sector, and must agree to use any income for research or teaching. In return it will be allowed to arrange the licensing of the patented results with a minimum of government interference.

Many current complaints about the patent system are addressed in a bill passed by the Senate last autumn, and sponsored by senators Birch Bayh and Robert Dole. If passed by the House, this will formalise a university's right to profit from the discoveries of its scientists in a manner simila to the Administration's proposals.

Others, however, are worried that t corporatisation of university research, a stretches down to the workings of the c may reinforce a philosophical reductionism already responsible, it is claimed, for the destruction of natural ecosystems and the increasing alienation of humanity from nature. ☐

The ties that bind or benefit

As industrial corporations become more involved in developing new biological techniques, where does this leave the scientist? How will university biology departments maintain their integrity and autonomy? How will individual scientists react t[illegible] and corporate demands? These and other questions were exp[illegible] when *Nature* brought together **Sheldon Krimsky**, Acting Direct of the Program in Urban, Social and Environmental Policy a Tufts University, and **David Baltimore**, Professor of Biology at MIT.

Krimsky: I am very concerned about the growing influence of industry on academic science. This has existed for many years in the chemical and the nuclear industries. And now it is beginning to occur in the biological sciences, especially with the advent of advances in recombinant DNA.

The direction of research influenced by industry may not be the direction that is in the public interest. Corporate requirements for scientific research may be at odds with pressing societal needs. There are many examples one could cite, especially in environmental research, nutrition and biomedical science.

Our academic institutions and academic scientists need to be free from corporate influence. And such influence can emerge in various ways: through direct funding by corporations to departments and investigators, by scientists serving as consultants to or on advisory boards of industrial firms, or by academic scientists playing a double role by setting up their own small venture-capital firms.

These are dangerous moves if they become widespread because in the end university-based science will lose its sense of detachment. When confronted with policy decisions on the applications of technologies to society we need objective academic involvement. How can the public have confidence in the expert opinion of scientists on the potential risks and benefits of a technology when those same individuals have financial interests in commercial development?

Baltimore: It seems to me that there is nothing wrong with universities serving as a source of technical expertise for newly developing industries or even for mature industries. And that kind of symbiosis between industry and academic departments has been very good for both over history — take the chemical industry.

This seems to be a healthy development for a number of reasons. One is that if there is an industrial use for modern biological techniques, it means that those who are trained in university biological laboratories will have an increased range of employment opportunities. With the recent lateau of hiring into academic positions, it necessary, if we are going to maintain aduate student activity, to find other oportunities for our graduate students.

What's more, we find that after the large investment in basic biological research we are now beginning to get practical spinoffs. While society may value the advancement of abstract knowledge, that is not society's major interest. Consequently, I find it heartening that we can now say to the public, "You've been investing all this money for so long and now things are emerging that are of practical value."

I, too, worry about the academic enterprise being undermined by corporate interests. We can have both an academic focus and industrial involvement but we must maintain a separation between the two. To make certain that university biology departments maintain their autonomy we must be vigilant about a number of things:

- We must be entirely open about industrial affiliations.
- We must maintain a separation between university and industry. When academics consult for industry to help find solutions to industry's problems, they ought to remain consultants and not turn their laboratories into factories for the solution of corporate problems. To be independent, university laboratories must be allowed to follow the internal logic of science.
- We should not use our students for our own ends. Students should continue to have freedom to work out problems that emerge in the laboratory, without being tied to predefined industrial needs.

If we can handle this mixed economy with honesty and integrity, we will have done a service to the university by bringing in new sources of funding and by increasing the importance of the university to industry.

Krimsky: In the 1960s, many scientists (including yourself) expressed moral outrage in learning of the war-related research carried on secretly at many universities. Now we must ask ourselves what the consequences will be if industries ostensibly fund entire departments (as they have done in chemistry, computer sciences, engineering and, more recently, certain areas of policy analysis). Notwithstanding the fact that corporations claim they give with no strings attached, we can [illegible] that they will establish the [illegible] of research. And second, "chilling effect," par[illegible]-funded faculties [illegible]ojects or express [illegible]eted as dis[illegible] corpor[illegible]related

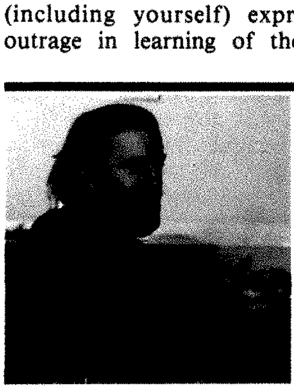
the ticul are inc views th advantage ate benefa academic re generation of sci a similar demise in corporate funds hav over academic research

Crucially, during perio[illegible] a about the risks of techno[illegible] independent scientists willing Risks may crop up in research the ultimate marketing of b products. As you know, in the chemical industry we have had ver scientists willing to speak out against potential hazards of petrochemical agent to workers, consumers or military personnel. And now we are faced with the results of their timidity. With so many scientists working directly from the chemical industry, can we expect them to speak freely about the toxic effects of chemicals? How extensive is the influence of industry on biology going to be?

Baltimore: I couldn't agree more. I think it is extremely important that the academic enterprise maintain its freedom to do what it wants, to say what it wants, to be counter to conventional wisdom and to discover things that are counter to the desires of industry.

Nevertheless, the positive side of industrial involvement in the academic world should not be discarded out of fear that university-based scientists will lose their autonomy owing to industrial pressure. We need to maintain a balance between industrial influences and influences from outside the corporate world.

Krimsky: Are there any mechanisms



Krimsky:
'Just as war-related research compromised a generation of scientists, we must anticipate a demise in scientific integrity when corporate funds have an undue influence over academic research'

0028-0836/80/02130-02$01.00

available to universities guaranteeing that balance? And as for spin-offs: what role does society play in determining what the research priorities or the practical applications of biological research ought to be? We can have many different kinds of potential spin-offs. Shall we simply allow corporate management to decide autonomously what path to take? Scientists may feel free to choose the fine-structured problems in a research programme at the same time that the shape of the outer boundaries of that programme are exogenously determined. It is in this important respect that science does not develop from some internal logic. I want to see more public and less corporate influence in establishing the outer boundaries.

Baltimore: In the United States the answer to your question is that the desire of people to seek profits determines what research gets turned into useful products for the general economy. If they are not even seen as potentially profitable, they are not pursued or produced. One can argue persuasively that that is not a sufficient reason and that government ought to play a larger development role.

Behind these kinds of disputes stands a naive model: at one side there is a scientific sector with people doing basic research. On the other, independent of basic research scientists, we have the industrial sector, selecting those areas for practical exploitation and deciding how they are to be applied. There is a much more important, neglected relationship. The shape of the outer boundaries of basic research is not merely influenced by the corporate sector alone, either directly or through government, but emerges from research itself. I see the world-wide research effort as a continuum — from the problems determined by the inner logic of science to the problems determined by outside influence.

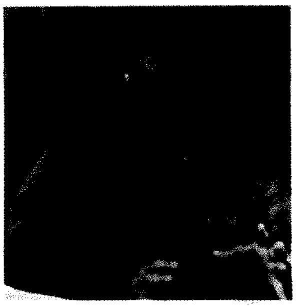
Many scientists work totally out of the logic of their research as it evolves in front of them. For them it doesn't matter what the rest of society thinks about the utility of what they are doing. These are the projects that in the end often turn out to produce the real surprises. No corporation can control them because no-one can see where they are heading.

At the other end of the continuum there are people doing contract research who have been asked to solve specific problems that industry or government wants solved.

Some research is a mixture: scientists get a little money to do something, trying perhaps to cure a disease and at the same time they discover new phenomena. They then have the freedom to explore these new areas.

Krimsky: How are we going to maintain a sufficient number of biologists not tied to the industrial sector, willing to stand up and say: "Wait a minute I am not very confident"? Remember it didn't happen in the petrochemical industry.

Baltimore:
'The positive side of industrial involvement in the academic world should not be discarded out of fear that scientists will lose their antonomy owing to industrial pressure'



Baltimore: Yes, there ought to have been much more questioning of what was going on. Universities should have opened up the debate. The rush of industrial development following World War II undercut the critical function of universities.

We now should look at the strengths of what has happened in the last five to ten years. The environmental movement has been a significant success in its own terms, even though it has not accomplished everything it wanted to. It never will. Nonetheless, it has moved from nowhere to become a major force in our society. That has happened because it has been supported by large groups of people.

Krimsky: But what about the scientific community?

Baltimore: In fact, many of the leaders in these movements have been scientists. Matthew Meselson, for example, is one of the best-recognised scientists in the academic world and yet he is the person who became most identified with opposing defoliation in Vietnam. The movement to stop biological warfare research (which even I had something to do with) came from inside the scientific community, again led by Dr Meselson. The movement to inhibit the development of recombinant DNA research (which, to my mind, got out of hand) came from within the scientific community.

Or consider Bruce Ames, the one person who has really brought a new dimension to our thinking about environmental dangers associated with cancer. He is one of the most eminent scientists in the United States. The Ames test revolutionises our understanding of the dangers inherent in everyday life. This seems to me to be most responsible action, coming directly from the scientific community. Now in fact industry uses the Ames test widely.

Krimsky: But industry has systematically opposed the Ames test as an instrument for establishing policies regarding potential human chemical carcinogens.

What's more, industry has set up its own cadre of scientists and experts to legitimate its opposition to effective testing. The American Industrial Health Council, the American Tobacco Institute and the Chemical Manufacturing Association have all set up private institutes designed to defend their positions and I'm worried that the influence of these institutes will spread into the biological departments of universities.

We do not have sufficient checks and balances. We cannot continue to allow university departments and individual scientists to exercise their own judgements because large amounts of money are likely to be derived from consultancies and from profits from these new biological technologies.

What we need is an independent source of funding, encouraging research on the dangers which might emerge from the new biological technologies. We need to secure the university against undue influence by industry in this new field. There must be a balance between research on developing new technologies and research on the potentially adverse effects of these developments.

Baltimore: I agree that we need to strongly counter attempts by industry to undercut legitimate, validated testing.

Krimsky: One way to accomplish this would be to give incentives to industry to fund universities indirectly through government agencies. Let the government funding agency distribute support to universities rather than allowing corporations to provide direct funding to departments of biology.

But why should industry do this? Clearly, corporations want to be able to direct research at universities and control the purse-strings.

If such funding went through agencies like the National Science Foundation or the National Institutes of Health, peer review committees could distribute the funding to appropriate university-based laboratories. The public would then have some way of overseeing the way the money was spent. We would then not end up with a closed, insulated system.

Baltimore: Where industry directly supports research in a given laboratory, that fact should be on record. One can then see in context the views of a scientist funded by industry when that research worker participates in discussions of work funded by the supporting corporation.

Krimsky: Given that scientists play multiple roles — for example there are those who are faculty members at universities, who also consult for industry and, in addition, sit on government advisory panels — shouldn't these multiple roles b on the public record?

Baltimore: To the extent that it does n unreasonably interfere with a perso s private life, I think it ought to be avail le information. □

NEWS AND VIEWS

Small RNAs and splicing

from Richard Roberts

THE small RNAs found in the nuclei of eukaryotic cells (snRNAs) were first described by Weinberg and Penman more than 10 years ago. They range in size from 90 to 220 nucleotides, are only found in the nucleus and have unusual 5′-terminal structures. These structures resemble the 'cap' structures of eukaryotic mRNAs but contain 2,2,7-trimethylguanosine rather than 7-methylguanosine as the blocking residue. They also contain some additional modified bases notably pseudouridine and 2′-O-methyl nucleosides. Although several (U1, U2, UU3B) have been sequenced by Busch and his colleagues, their function is unknown. This may soon change however as a new experimental attack has been launched which could lead to fresh insights into both the function of these snRNAs and the processing of initial RNA transcripts.

Experiments described in two recent papers (Lerner & Steitz, *Proc. natn. Acad. Sci. U.S.A.* **76**, 5495; 1979 and Lerner *et al.*, this issue of *Nature* page 220) have uncovered an interesting class of subnuclear particles and provide the basis for some fascinating speculation about 'RNA splicing.' The experiments are based on old reports (Mattioli & Reichlin *J. Immunol.* **107**, 1231; 1971; Northway & Tan, *Clin. Immunol. Immunopathol.* **1**, 140; 1972) that certain patients suffering from systemic lupus erythematosus possess circulating antibodies directed against a ribonucleoprotein complex present in the nuclei of many eukaryotic cells. In the first paper, Lerner and Steitz have characterised the RNA and protein components of this complex. They show that the complex contains a specific set of seven polypeptides with molecular weights between 12,000 and 35,000, which are neither histones nor the polypeptides associated with the 30S hnRNP particles. The RNA components are the small nuclear RNAs described above. Different antisera precipitate different subsets of these small RNAs, but always with the same set of seven polypeptides. Furthermore, the experiments show that the snRNAs may be quantitatively precipitated from nuclear extracts in the form of these ribonucleoprotein complexes. The authors propose that each snRNA can interact with the same set of seven polypeptides to form a discrete ribonucleoprotein particle (snRNP).

A further step in the characterisation of the snRNPs is described in this issue of nature (Lerner *et al.*). First it is shown that the lupus antisera precipitate similar snRNP complexes from a variety of eukaryotic sources, ranging from man to insect, indicating that these complexes have been highly conserved during evolution. They are not found, however, in tobacco, yeast, *Dictyostelium discoideum*, or *E. coli* extracts. They are present in highest abundance in metabolically active cells, and from such cells they sediment, in sucrose gradients, with a molecular weight (30S) far greater than that observed (7-10S) for the free snRNP species. This suggests that the 7-10S particles are themselves bound to some other moiety of much higher molecular weight. The authors speculate that the high apparent molecular weight may be due to the attachment, of the snRNP particles, to hnRNA, which is itself associated with 30S hnRNP particles.

The arguments leading to this prediction, while not compelling, are highly intriguing. Several groups have examined the sequences present around the splice junctions in hnRNA and defined a consensus sequence from which any one sequence diverges by only a few nucleotides. This is postulated to be a 'preferred' sequence at which splicing could occur. By examing the sequence of a major snRNA (U1A), the authors noted that its 5′-terminal sequence shows extensive complementarity to this preferred sequence. Nucleotides 3 to 8 from U1A exactly match that part of the 'preferred' sequence found at the 5′ end of the intervening sequence, while nucleotides 9 to 11 exactly match the 3′ end of the intervening sequence. Some further possibilities for base pairing exist between nucleotides 12 to 20 of U1A RNA and the continuation of the 3′ intervening sequence. Thus it is hypothesised that the 5′-terminal sequences of U1A RNA interact with the terminal sequences of the intervening regions and thus serve a template function by correctly aligning the sequences to be spliced. Consistent with this role for the 5′-terminal sequences of U1A RNA is the finding that among the snRNP particles is a minority class which does not show the high apparent molecular weight in sucrose density gradients. This class contains a shortened form of U1A RNA which is missing both the 5′ terminal 'cap' structure and the first six nucleotides from the 5′ end. The absence of these nucleotides would seriously disrupt the fit required by the model. It is not known whether these particles, containing the shortened form of U1A RNA, are an artefact of isolation or have metabolic significance.

A similar scheme has previously been proposed in the adenovirus-2 (Ad2) system, this time invoking the Ad2 encoded VA RNA as a template for the processing of late Ad2 mRNAs (L. Philipson, unpublished *News & Views* **277**,593; 1979; Murray & Holliday FEBS *Lett.* **106**, 5; 1979). Here, the detailed model of Murray and Holliday seems less attractive since it requires base pairing with nucleotides which lie beyond the known 3′ end of VA RNA. Whatever the final outcome of these predictions, it seems that at last an experimental system is available for the study of RNA processing events within the eukaryotic nucleus and such studies should be spurred by the tantalising hypothesis developed in this latest report.

Amidst the frenzy of activity presently aimed at cloning and sequencing DNA, we should perhaps remember that many of the highly conserved processes of molecular biology involve only RNA and protein. The specificity of protein synthesis is provided by the triplet interaction between tRNA and mRNA, while its initiation requires RNA-RNA interaction between the 3′-end of ribosomal RNA and mRNA. The ribosome which catalyses this process contains both RNA and protein and recently an RNA processing enzyme,

RNase P of *E. coli,* has also been shown to consist of both RNA and protein (Stark *et al. Proc. natn. Acad. Sci. U.S.A.* **75,** 3717; 1978). Some of us would argue that this reflects the early establishment of these processes during evolution, at a time preceding the arrival of DNA on the biological scene. If RNA splicing is also a process which developed at an early stage in evolution (*News & Views* **272,** 581; 1978; Darnell, *Science* **202,** 1257; 1978) then it may not prove surprising if its specificity also depends upon RNA-RNA interactions. ☐

Galaxies: the origin of spiral structure

from M.G. Edmunds

A RECENT comparison of the morphology and rotational properties of nearby galaxies, together with computer simulations of a simple model of patterns of star formation, may have greatly clarified our understanding of the causes of the beautiful spiral structures seen in many large systems. The origin of such structure remained a source of speculation for many years until during the 1960s the formulation of a 'density wave' theory seemed to provide a suitable physical mechanism. A clue lay in the fact that well-developed spiral structure is seen only in galaxies with disks containing both stars and gas. The basis of the theory is the propagation around the centre of the galaxy of a perturbation in the space density of stars. The gas in the interstellar medium responds strongly to the perturbation in the gravitational field, and its compression results in a shock wave which instigates the gravitational collapse of gas and dust to form stars. It is the very non-linear behaviour of the gas which gives rise to the large influence on the overall appearance of a galaxy for only a small perturbation in the underlying distribution of stars. Of the stars which form, the massive ones are extremely luminous, and it is they which are seen delineating the spiral pattern. Such stars are short lived and soon die out, leaving the wave to show itself by new star formation as it moves relative to the interstellar gas. The pattern of the wave rotates 'rigidly' around the galaxy's centre, although the gas in stars may be in differential rotation — and hence relative shearing motion. The extent of the differential rotation is governed by the overall gravitational field experienced by the stars and gas particles.

Unfortunately a fundamental difficulty arose in understanding how the spiral wave manages to maintain itself against dissipation. A particularly important dissipating process will occur at the so-called 'inner Lindblad resonance'. A star in a galaxy will have a bounded orbit around the centre, but the orbit will not normally be either circular or closed. The intervals between the star being at some particular distance from the centre will, however, be well defined with the frequency of successive inward or outward passages being called the 'epicyclic' frequency, and this is determined by the local gravitational field. Now if the frequency of successive passages past the star of the density wave perturbation in gravitational field exactly matches the epicyclic frequency at that radius, then the star will experience acceleration due to the perturbation at the same point on successive orbits. A resonance will hence occur which will feed energy out of the density wave and into the velocities of the resonated stars. The problem for the density-wave theory is to replace this loss of energy, and no obvious method exists for a single isolated galaxy with a simple pure spiral pattern. A way round the difficulty would be to show that isolated spiral galaxies which show good spiral structure do not have inner Lindblad resonances. No resonance would occur if there were no differential rotation, since the pattern speed in this case will never match the epicyclic frequency.

Such behaviour has indeed been found by J. Kormendy and C.A. Norman (*Astrophys. J.* **233,** 539; 1979) in a discussion of the morphology of some 54 spiral galaxies for which rotation velocities are available. Those galaxies which are on their own and have well-developed spiral patterns do not differentially rotate over the region where the spiral structure is apparent. The galaxies must be able to find enough energy transfer to overcome any other (less important) dissipation of the wave. But these galaxies represent only one-fifth of the sample. Over half the sample do differentially rotate and hence are expected to have an inner Lindblad resonance. Yet they still show good spiral structure, the difference being that the differential rotators either have a nearby companion galaxy or else have a bar structure in their centres. An example of a barred galaxy is shown in Fig. 1, and a less

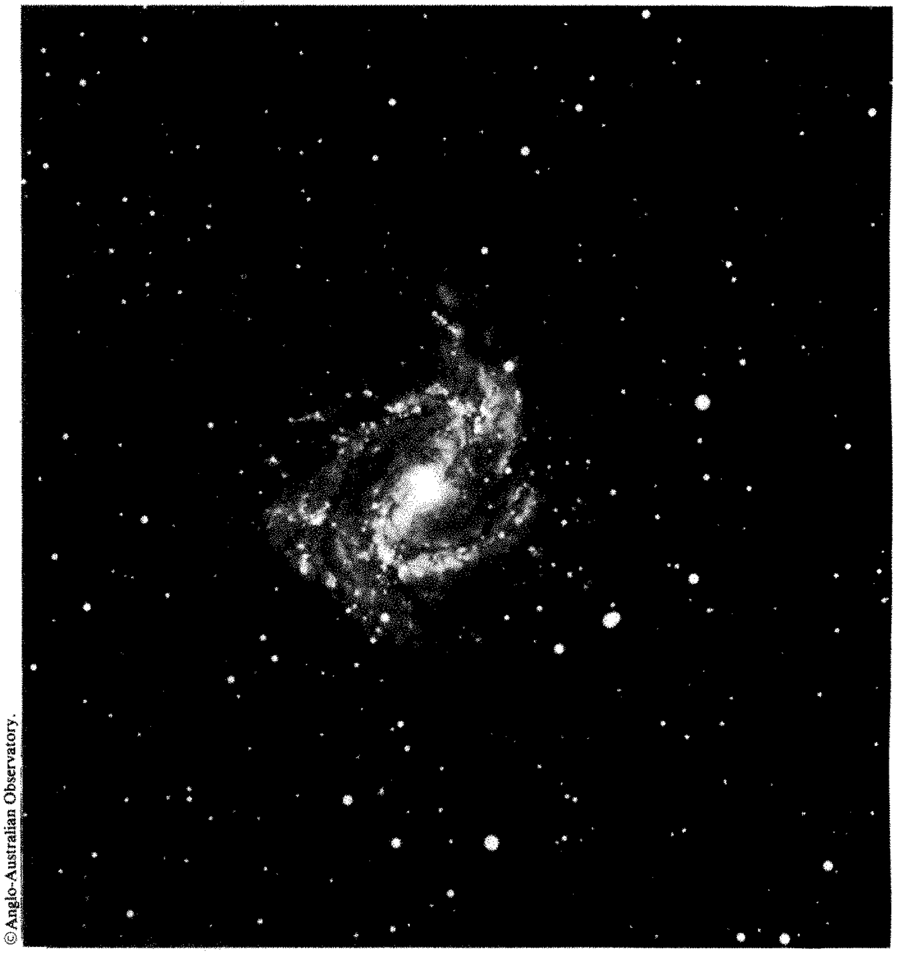
M.G. Edmunds is a lecturer in the Department of Applied Mathematics and Astronomy, University College, Cardiff.

0028-0836/80/02133-02$01.00

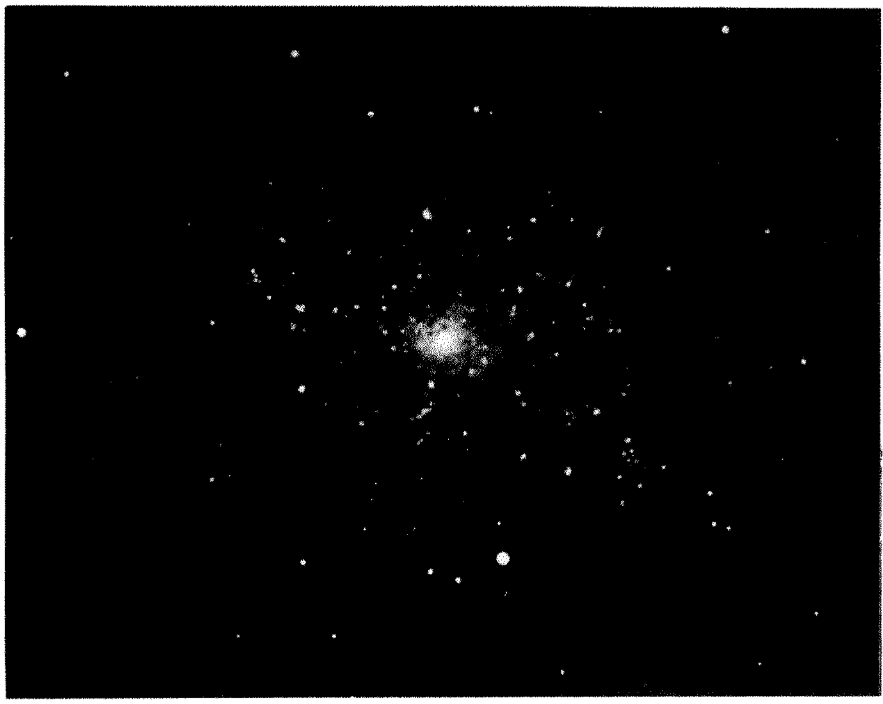
extreme (but still barred) case in Fig.2. The importance of the companion or bar is in providing a significant rotating non-axisymmetric gravitational potential which will 'stir' the galaxy and force the spiral structure. The pattern is still the result of a density wave, but the driving of the wave will presumably replenish the energy lost at the inner Lindblad resonance. The initial formation of the bar presents no problems, since numerical simulations of the stellar dynamics in galaxies show a particular willingness to evolve rapidly to give a central bar.



©Anglo-Australian Observatory.

Fig.2. NGC 5236 (M 83) showing a less obvious, but still important, central bar.

There still remains a significant fraction of galaxies in the sample which differentially rotate, but have neither bar nor companion. An example of the morphology of this type of galaxy (although not one from Kormendy and Norman's sample) is shown in Fig.3. The spiral structure is very fragmentary, with no grand two-armed design, but rather a system of multiple and branched arms which can only be individually followed over short distances. P.E. Seiden and H. Gerola (*Astrophys. J.* **233**, 56; 1979) have developed a series of computer models which nicely simulate such structures, and show that it may have very little at all to do with a global density wave pattern. Their model supposes that the supernova explosion of the bright massive stars which illuminate spiral structure can produce further star formation, since the shock which the explosion pushes out into the interstellar medium may induce the collapse of nearby interstellar clouds. The new massive stars formed would subsequently also explode, and so the star formation would propagate through the galaxy. Strong differential rotation of the disk would tend to pull such regions of star formation out into an arc — causing a short spiral arm. An element of randomness is introduced by allowing some spontaneous star formation, and the correlated activity which gives rise to structure is produced by having a higher probability for the supernova-induced star formation. Since there is some evidence from supernova remnants in our own Galaxy that such induced star formation can occur, Seiden and Gerola's model is attractive, and must also play some part in influencing the morphology of spiral arms even when a large-scale density wave is operative.



©Anglo-Australian Observatory.

Fig.3. NGC 7793 showing multi-armed, filamentary spiral structure.

Life would not be so interesting without exceptions, and two unusual galaxies turn up in Kormendy and Norman's sample. These are both isolated single-arm (as opposed to normal double-arm) and they differentially rotate, although the spiral arm in one of them (NGC 4378) can be traced over almost 1¼ revolutions. But the fact that only two cases out of a sample of 54 cannot be immediately classified is surely encouraging.

There remain lingering theoretical problems connected with preventing a stellar disk from becoming too unstable to bar formation without either an unacceptably large velocity dispersion among the stars or a rather *ad hoc* massive halo of low luminosity objects surrounding the disk. Despite this, the three mechanisms — a self-sustaining two-armed density wave in the absence of an inner Lindblad resonance, a density wave driven by the gravitational perturbation from a stellar bar or companion galaxy, or stochastic supernova-induced star formation with differential shear in the disk — seem to provide a reasonable basis on which to account for the structure of spiral galaxies. □

Carcinogens and DNA

from Stephen Neidle

THE physical and chemical properties of the potent diolepoxide carcinogens have been much studied in the hope of determining the molecular basis of their carcinogenic and mutagenic effects. They are known to bind directly to DNA, and this reaction has formed the focus of both experimental and theoretical investigations into the activity of diolepoxides such as benzo(*a*)pyrene 7,8 dihydrodiol 9,10 oxide, the most important active carcinogenic metabolite of benzo(*a*)pyrene.

Although theoretical approaches to the likely conformation and chemical reactivity of the four possible stereoisomers of benzo(*a*)pyrene diolepoxide, using quantum-mechanical methodology, have had great influence on thinking in this field, in many cases the theoretical findings conflict with the experimental evidence and it is fair to say that only some of the recent theoretical treatments are successful or other than trivial in their predictions. The deficiencies and limitations of some approaches are highlighted for example, by their inability to explain satisfactorily the considerably greater tumorigenicity and DNA binding ability of the *anti* compared with the *syn* isomer (Brookes *Cancer Lett.* **6,** 285; 1979), even though the theoretically-derived data indicate that the *syn* isomer is the more stable (Klopman, Grinberg & Hopfinger *J. theor. Biol.* **79,** 355; 1979) and until relatively recently was believed to be the biologically significant one.

Application of the ϕX174 DNA assay system developed by Harvey and coworkers to a series of diolepoxide carcinogens, has led to the revelation of further deficiencies in some quantum mechanical analyses (Hsu *et al. Biochem. biophys. Res. Commun.* **87,** 416; **88,** 1; 1979). This assay system is remarkably effective in correlating inhibition of viral infectivity with carcinogenic potency of the various diolepoxides, yet this correlation was not followed either by predictions of reactivities from molecular orbital theory or by the relative structure positions of the diolepoxide groupings on the hydrocarbon skeletons.

Clearly, studies of the chemicals themselves are not enough to explain their different carcinogenic potencies and other factors such as the geometry and kinetics of their binding to the DNA receptor sites will have to be taken into account.

Benzo(*a*)pyrene diolepoxide carcinogenesis is generally considered to involve direct binding to DNA, with guanine residues as the major sites of attachment at least in terms of stoichiometry. About 10% of the total binding is to adenine however, and although its significance is unclear, some recent evidence correlates binding to adenines and not to guanines with mouse skin tumorigenicity (Di Giovanni *et al. Cancer Lett.* **7,** 39; 1979), although in this report no adducts have actually been characterised as diolepoxide ones. Adenine-modified regions of DNA are known to have rather different conformational properties in terms of greater local denaturation than their guanine counterparts. The *anti* form of the diol epoxide can be resolved to two stereoisomers. Their interactions with DNA are, not surprisingly, stereospecific (Meehan & Straub *Nature* **277,** 410; 1979), with essentially only the (+) isomer binding to double-stranded DNA (to guanines) whereas denatured, single-stranded DNA was equally susceptible to both isomers. These differences in binding ability correlate with biological activity in several cell lines — the (+) isomer being more carcinogenic — and Meehan and Straub suggest that DNA secondary structure is an important determinant in carcinogenicity.

One question of interest in looking at the binding of carcinogens to DNA is whether any specific base sequence is involved. Weinstein, Grunberger and coworkers (*Biochemistry,* in the press) do to a large extent confirm Meehan & Straub's findings, with the additional important observation from restriction enzyme analysis of modified SV40 and lambda DNA, that no appreciable specificity of binding in respect of base sequence was apparent. However, subtle and possibly important effects of binding specificity may occur. Probably more crucial to carcinogenicity is the geometry of the binding in relation to subsequent excision repair by endonucleases. Binding to different residues and different chemical groups within a residue dramatically affects excisability. Increased excisability implies attachment on the outside rather than to deeply buried sites within the molecule.

There is no lack of molecular models for the structure of benzo(*a*)pyrene diol epoxide-modified DNA, some of which owe more to imagination than to reality. The recent suggestions of Beland (*Chem.-Biol. Interactions* **22,** 329; 1978) are among the more plausible and detailed with the benzo(*a*)pyrene chromophore being situated in the DNA minor groove and causing some local denaturation of the double helix. This general type of non-intercalative model is strongly supported by several recent physical measurements on the diol epoxide–DNA complex. Fluorescence probe techniques (Prusik *et al. Photochem. Photobiol.* **29,** 223; 1979; Prusik & Geacintov *Biochem. biophys. Res. Commun.* **88,** 782; 1979) give data consistent with the benzo(*a*)pyrene chromophore attached (by N2 of guanine) externally to the DNA double helix, and oriented with at most a 35° angle to the helix axis. In particular, intercalation (at least in the sense of the classical Lerman model) is ruled out by these workers on account of the accessibility of the chromophore to external probings. Additional evidence for a non-intercalative model is also provided by the new technique of optically-detected magnetic resonance (Lefkowitz *et al. FEBS Lett.* **105,** 77; 1979)

Unfortunately such techniques cannot provide detailed information on the molecular geometry of the modified residues of DNA. The situation is made yet more complex by the growing realisation that DNA structure is not always necessarily of the classical forms. There is now powerful evidence for example, that tracts of alternating pyrimidine-purine residues have highly unusual structures (see for example *Nature* **282,** 680; 1979; *News and Views,* **283,** 11; 1980); it would not be surprising if binding of carcinogens did not sometimes exploit such peculiarities. Molecular model-building of nucleic acid-carcinogen interaction urgently requires input of firm data from the fine structure techniques of X-ray crystallography and NMR in order to achieve credibility. Questions of the relevance of the structural peculiarities mentioned above to differences in excisability and repair, and to carcinogenic and mutagenic processes in general must await future investigations. ☐

The specificity of plant defences

from R.A. Dixon & C.J. Lamb

WHEN plants are attacked by bacterial or fungal pathogens they synthesise and accumulate nonspecific antimicrobial compounds known as phytoalexins. A few years ago it was established that phytoalexins could be induced to accumulate by glucan and glycoprotein 'elicitor' molecules associated with the cell wall of the invading pathogen (see *News & Views* **273,** 266; 1978) and this has started a search for the molecular basis of the exquisite specificity seen in the classical 'gene-for-gene' relationship between plant cultivars and physiological races of a pathogen, looked at in terms of elicitors and phytoalexin production.

In the simplest terms the gene-for-gene relationship consists of a gene for 'avirulence' in the pathogen being complemented by a specific one for resistance in the plant — the plant and pathogen are in this case incompatible.

R.A. Dixon is in the Department of Biochemistry, Royal Holloway College, University of London and C.J. Lamb is in the Department of Biochemistry, University of Oxford.

0028-0836/80/02135-02$01.00

Disease results when a mutation in the pathogen produces a new avirulence gene (now a 'virulence' gene) that is not matched by the available resistance genes carried by the host cultivar — the plant and pathogen are now compatible. Plant breeders have long been familiar with the ability of plant pathogens to keep one jump ahead by continually throwing up new races to which hitherto resistant varieties of crops are completely susceptible.

The simplest model for the gene-for-gene phenomenon in terms of elicitors requires that a race-specific elicitor (presumably the product of the pathogen's avirulence gene) is recognised by a specific receptor on the plant cell (presumed to be the product of the plant's resistance gene); phytoalexin production is induced and the pathogen is limited. If a mutation either in the pathogen or plant means that the elicitor is no longer recognised by the plant, then the infection is not limited and disease follows. The key predictions of this model are first, the existence of race-specific elicitors, and second, that the differential accumulation of phytoalexin is the most important determinant of disease resistance.

Recent work suggests that this model is indeed an oversimplification and that the real world is considerably more complex. On the question of race-specific elicitors Keen *et al.* (*Physiol. Plant Pathol.* **15,** 43; 1979) recently claimed to show race-specific elicitors in the cell envelopes of physiological races of the bacterium *Pseudomonas glycinea*, which causes bacterial blight in soybeans. High molecular weight glycoproteins solubilised by detergent treatment showed the same specificity, with one exception, in eliciting accumulation of the phytoalexin glyceollin in cotyledons of two varieties of soybean as did the bacterial races from which the elicitors were isolated.

In contrast, however, Albersheim and coworkers (*Plant Physiol.* **57,** 760; 1976) have shown that glucan elicitors from four different races of the fungal pathogen *Phytophthora megasperma* var. *sojae* (Pms) are qualitatively and quantitatively identical suggesting that further 'specificity factors' are needed to account for race-specific resistance. A recent report by Wade and Albersheim (*Proc. natn. Acad. Sci. U.S.A.* **76,** 4433; 1979) now identifies glycopeptides secreted into the culture medium by Pms as the proposed factors. Glycopeptides from three races of Pms were tested for their ability to prevent the expression of serious symptoms in four soybean cultivars. Glycopeptides from incompatible races of the pathogen but not from compatible ones protected seedlings from attack by compatible races. Glycopeptides from compatible races did not cause cultivars resistant to a given Pms race to become susceptible to that race. The glycopeptides themselves are only weak elicitors and their effect on glucan elicitor action remains to be established. Wade and Albersheim postulate that synthesis of the glycopeptides is controlled by the pathogen's avirulence genes and that in incompatible but not compatible interactions they trigger a defence reaction which decreases the rate of pathogen development and enables inhibitory levels of phytoalexin to accumulate in the area of initial fungal penetration.

Such a hypothesis still leaves open the nature of the proposed defence reaction and the product of the host's resistance gene. This model assumes no determinative role for elicitor-induced phytoalexin accumulation in the soybean-Pms system and indeed Albersheim and coworkers (*Plant Physiol.* **57,** 760; 1976) have shown that initial rates of glyceollin accumulation are identical during infection of wounded hypocotyls by compatible and incompatible races of Pms. This contradicts earlier work of Keen (*Physiol. Plant Pathol.* **1,** 165; 1971) who observed differential rates of glyceollin accumulation in this system. However, in both studies no account is taken of the cellular and subcellular distribution of glyceollin and such considerations may be crucial for a full understanding of the role of phytoalexins in race-specific resistance.

A common feature of the models of Keen and Albersheim is that specificity is associated with the incompatible interaction. However, this may not always be the case. Two recent papers by Kuć and coworkers (*Physiol. Plant Pathol.* **15,** 117 and 127; 1979) suggest that in potato cultivars with R genes, specificity in resistance to physiological races of *Phytophthora infestans*, the causal agent of potato blight, is associated with compatibility, and a phytoalexin suppressor, or 'hypersensitivity inhibiting factor' is proposed as the determinant of specificity. They found that mycelia and zoospores of a compatible race of *P. infestans* contain β, 1-3, β, 1-6-linked low molecular weight glucans which could inhibit the rapid cell death, loss of electrolytes, tissue browning and accumulation of terpenoid phytoalexins associated with the hypersensitive reaction of potato tissues to treatment either with elicitor from the same compatible race or infection by an incompatible race. Although the incompatible race contained similar glucans they were much less active as suppressors of the hypersensitive reaction.

The glucans consisted of non-anionic and anionic fractions, the latter containing a small proportion of glucose residues as phosphoryl monoesters. In preliminary experiments, mixing elicitors from compatible or incompatible races with a membrane preparation from potato tubers led to decreased elicitor activity on subsequent application to tuber tissues, possibly as a result of sequestration of elicitors by binding sites on the membrane preparation. Only glucans from the compatible race were able to restore elicitor activity, suggesting that the small glucans may compete for the elicitor binding sites. These molecules may prove valuable tools in the search for elicitor receptor sites. Elicitors from *P. infestans* agglutinate potato protoplasts indicating cell surface binding sites (*Science* **201,** 364; 1978), but it is not clear whether these sites are receptors for elicitor induction of phytoalexin accumulation.

Although no unified hypothesis has yet emerged, the demonstration of molecules that determine specificity in plant–pathogen interactions is a major development in the study of the molecular basis of race-specific disease resistance. Clearly there is considerable scope for collaboration between biochemists and pathologists in this important field. □

Patterns of ungulate reproduction

from Robert M. May

ONE theme, around which much current ecological research is organised, concerns the relation between an animal's physical and biological environment (its habitat and the species it interacts with) and its foraging and reproductive behaviour. In this context, Robbins and Robbins (*Am. Nat.* **114,** 101; 1979) have recently drawn together a lot of data on ungulate and subungulate species, with a view to elucidating fetal and neonatal growth patterns, and trends in maternal reproductive effort. These authors believe ungulates to be especially interesting, because they inhabit a wide range of environments, and comprise species in many different stages of domestication.

By plotting the weight of the fetus (expressed as a fraction of the weight at parturition) as a function of time (expressed as a fraction of the gestation period) for several species, Robbins and Robbins show the fetal growth rate in ungulates is a power function that varies little among species, and is typically of the general mammalian pattern derived by Sacher and Staffeldt (*Am. Nat.* **108,** 593; 1974) and others. Using data for white-tailed deer, domestic sheep and cattle, they also show the weight of the actual fetus, as a percentage of the gravid uterus, increases steadily throughout gestation, to around 60% at parturition. The pattern shows no significant differences between natural and domesticated ungulates; that is, selection for a larger neonate in domesticated animals entails a proportional enlargement of the uterus, fluids and membranes. As Robbins and Robbins point out, this fact

---

Robert M. May is Class of 1877 Professor of Zoology at Princeton University.

suggests "The efficiency of the reproductive process in terms of fetal energy or matter produced per unit of uterine tissue may already be selectively maximized" in natural populations. Similarly, under maternal nursing the maximum growth rates of newly born animals ('neonates') of different species increase in a systematic fashion with increasing maternal weight, with no significant differences between natural and domesticated ungulates. Estimates of the average milk production at the peak of lactation by well-nourished females, nursing a single neonate, also reflect no more than a systematic, curvilinear increase with increasing maternal weight.

The relationship between weight of offspring at birth (expressed as a percentage of maternal weight, or 'proportionate birth weight') and average maternal weight is shown in Fig. 1, for some 69 species. We see the maximum relative reproductive effort apparently occurs in pronghorn antelope and springbok, at around 15%, and decreases to around 4–5% for the very large ungulates and subungulates. The trend to diminishing proportionate birth weight with increasing maternal weight is fairly steady for the larger animals, but there is much variability among the small species (adult weights less than or around 100 kg). Although there is too much scatter for any crisp generalisation, Fig. 1 shows that several north temperate and arctic ungulates (for example, caribou, muskox, bighorn sheep) tend to produce relatively smaller offspring than most African ungulates, with North American species typically being intermediate. The explanation for the relatively small single fetus of caribou, muskox and bighorn sheep may lie in "Inadequate food supplies during winter and the need to optimize maternal survival relative to reproductive effort"; these factors apparently override thermodynamic considerations, which would argue for the largest possible neonate, to minimise heat loss in a cold environment.

As Robbins and Robbins emphasise, there are yet further complications among the smaller species represented in Fig. 1. The Mexican red brocket deer, a shy tropical animal which has one of the lowest proportionate birth weights of the smaller ruminants, has a postpartum estrus. So do muntjac deer and several African bovids. These species live in relatively stable environments, and the combination of relatively low birth weight and postpartum estrus enables them to distribute reproduction throughout the year, in a way that may well increase total reproductive output.

In short, Robbins and Robbins' comparisons among species of ungulates and subungulates suggest that "very basic controlling mechanisms" may produce systematic patterns in fetal and neonatal growth, with these patterns being common to natural and domesticated species. The proportionate birth weights of the smaller species, however, tend to exhibit a fascinating richness of detail that overwhelms any easy generalisation. □

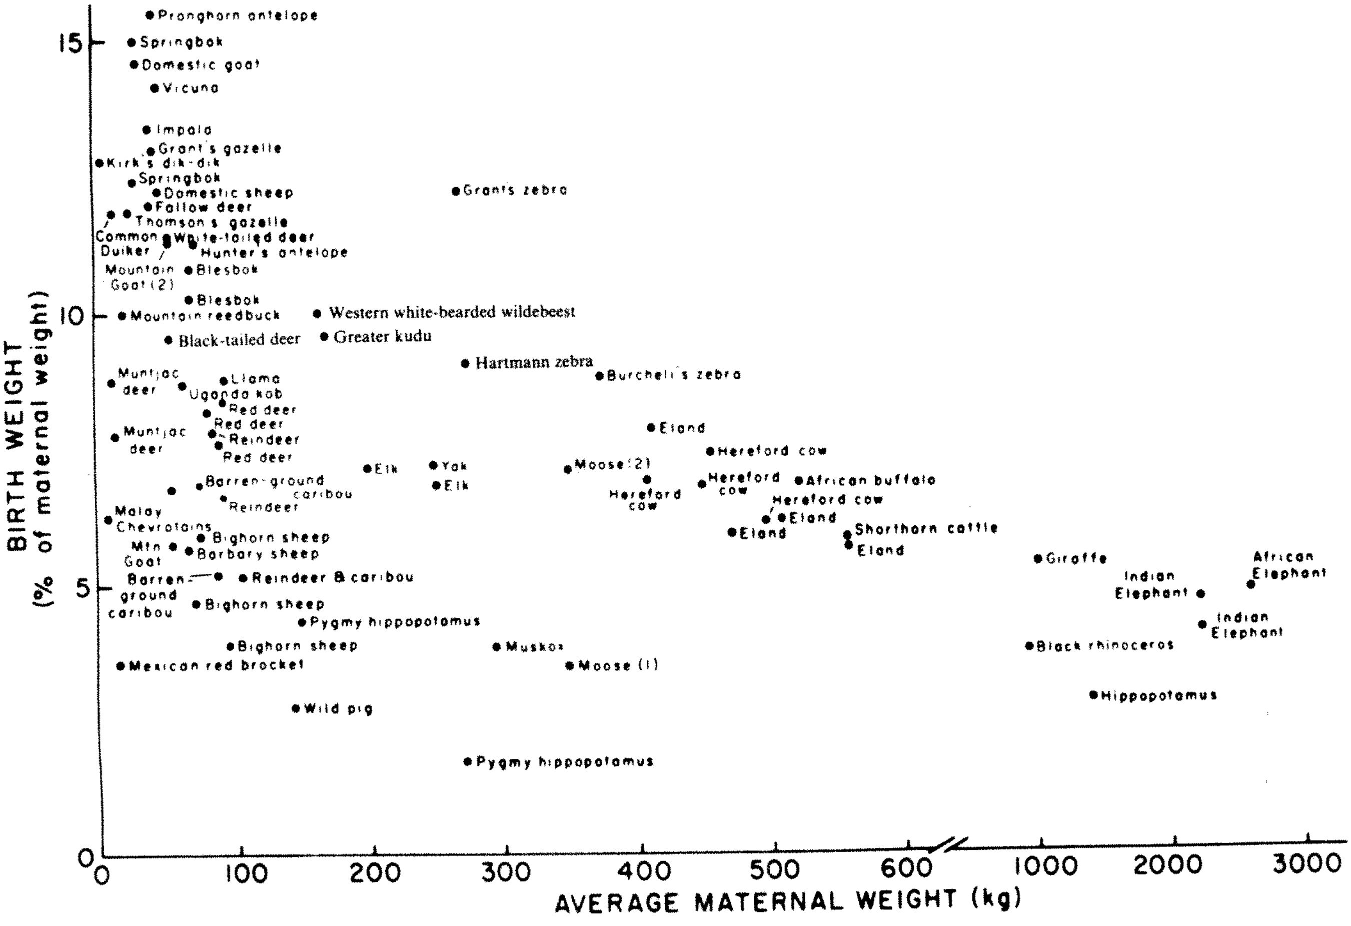

Fig. 1 Birth weight (as a fraction of maternal weight) as a function of average maternal weight in ungulate and subungulate species.

The non-linear spiral

from J. David Pye

THE sense organ of the ear is the cochlea which, as its name implies, is shaped like a snail's shell. Inside its hard, bony wall are three liquid-filled chambers that run together round the spiral from the base to the tip. One of the dividing partitions is a very thin, acoustically transparent membrane but the other, the basilar membrane, is an elaborate structure. It bears four rows of sensory hair cells that are connected by synapses to the ends of nerve fibres that run to the brain.

Sound-induced vibrations of the eardrum are efficiently transmitted to the incompressible cochlear liquids by a chain of three tiny bones. A relatively slow travelling wave is then initiated in the basilar membrane and its movement excites the hair cells. For high-pitched tones the travelling wave builds up quickly

0028-0835/80/02137-02$01.00

to a peak near the base of the cochlea and then decays while for deeper tones it runs further towards the tip, thus exciting a different population of hair cells.

The cochlea therefore, not only transduces sound energy into nerve signals to the brain but also acts as a mechanical frequency analyser. But despite extensive study, neither of these functions is well understood in detail, for the known properties have so far not yielded a satisfactory synthesis. New findings from several sources now suggest that some parts of the mechanical action are non-linear and this realisation has greatly stimulated both theoretical speculation and new kinds of observations.

The new developments were aired at a recent meeting in London* and some of the highlights are mentioned below. Non-linearity implies that a response is not directly proportional to its cause (the response curve is not straight); it also leads to the local generation of distortion products that are not present in the original stimulus. This is of course a common feature of any system that is 'overdriven' by excessive stimuli and indeed the beat-notes and other combination tones produced in the ear by loud sounds are already familiar. It is surprising, however, to find that the ear is markedly non-linear even at moderate and low sound intensities and that this property is related to active processes in the living organ.

Conventional linear models of cochlear mechanics have always presented problems and non-linear models which embrace some previously unexplained phenomena have been proposed. Indirect evidence of non-linear motion has been obtained by electrophysiological and acoustic techniques (D. O. Kim, Washington University).

Direct evidence of non-linearity has been provided by E. Lepage and B. Johnstone of the University of Western Australia, Perth, who measured movements of the cochlear partition in guinea pigs by a micro-capacitative probe. They were able to confirm the results of W.S. Rhode of the University of Wisconsin, Madison who had previously demonstrated non-linearity in monkeys by a less sensitive Mössbauer technique.

Further direct evidence was provided by D.T. Kemp (The Royal National Hospital, London) who discussed in detail his newly discovered mechanical evoked response or 'cochlear echo'. He and his collaborators have shown that brief sounds introduced into the ear canal can be detected again several milliseconds later as a vibration of the eardrum coming out from the cochlea. This is thought to occur because active non-linearity in the mechanical action of the basilar membrane would produce local changes in its impedance from which some of the energy will be reflected back towards the base of the cochlea. The involvement of active mechanical processes, using energy derived from physiological sources, was unexpected; but measurements of the echo show that under certain conditions it may contain more energy than is available from a passive reflection from that point. The theories of passive non-linearity that originally predicted the effect have therefore had to be revised.

The phenomenon has been independently confirmed by other workers (J.P. Wilson, University of Keele; H.P. Wit & R.J. Ritsma, University Hospital; Groningen; W.L. Rutten, Academic Hospital, Leiden; Kim). As the cochlear 'Kemp echo' has been shown to depend on normal physiological functioning of the living cochlea, its measurement can form a valuable new diagnostic tool. It is also related to the fine structure of the normal hearing curve (which is not smooth but shows regular, very sharply tuned peaks of up to 10 dB) and both responses can be detected by instruments at sound levels far below the audible threshold (Wilson). That the echo originates from mechanical non-linearity is further demonstrated by its relationship to the distortion products, especially the difference tone (f_2-f_1) and the cubic term ($2f_1$-f_2). Finally, it seems to be intimately linked with certain forms of tinnitus, where the cochlea oscillates spontaneously (for zero stimulus energy) and produces an objective tone that can be recorded from the eardrum.

In the field of psychoacoustic and electrophysiological observations, particular attention is being devoted to the physiologically vulnerable combination tones (f_2-f_1 and $2f_1$-f_2) and to the elusive 'second filter' that makes the responses of single nerve fibres more sharply tuned than the basilar membrane that excites them. Here again the properties of the cochlear echo (in response to paired stimulations) may provide a valuable new kind of evidence. But A.R. Palmer and E.F. Evans (University of Keele) found that single unit recordings from the acoustic nerve gave no evidence of mechanical non-linearity in the cochlea.

In discussions of cochlear mechanisms, of especial interest was the demonstration by A. Flock (Karolinska Institute, Stockholm) that the simple stereocilia of the hair cells are filled with actin filaments which also occur in the cuticular plate and round the apical circumference of the cell itself. The discovery of contractile proteins at these sites could be of great significance in understanding the transduction from mechanical to nervous (that is, electrical) energy and the part played by active, non-linear mechanical processes.

A.C. Crawford and R. Fettiplace (Cambridge University) showed that electrical stimulation of hair cells in the terrapin produces a finely tuned electrical response similar to that elicited by sound. The very short cochlea in the terrapin is probably an ineffective mechanical analyser and this discovery suggests that the second filter involves cellular processes. In the more traditional guinea pig, I.J. Russell and P.M. Sellick (University of Sussex) and Y. Tanaka (Dokkyo University, Tichigi) and his colleagues showed that the inner and outer rows of hair cells have very different response properties that may contribute separately to the final output of the cochlea.

It seems safe to predict that this meeting will come to be regarded as a milestone in the study of hearing. Hi-fi enthusiasts may be shocked, but non-linearity of the normal, healthy cochlea could be a key to its amazing performance. ☐

---

*A meeting on non-linear and active mechanical processes in the cochlea was held on 17-19 September, 1979 at the Institute of Laryngology and Otology of the Royal National Throat Nose and Ear Hospital, London. It was organised by Dr D.T. Kemp and Mr S.D. Anderson.

J. David Pye is Professor in the Department of Zoology and Comparative Physiology, Queen Mary College, London.

100 years ago

We pass on therefore to the lower marine animals, and select as an example of the way they are treated a rare British species allied to the sea cucumbers, and named *Synapta duvernea*. It was discovered in the English Channel by M. Quatre-fages, who thus describes it:-

"Imagine a cylinder of rose-coloured crystal as much as eighteen inches long and more than an inch in diameter, traversed in all its length by five narrow ribbands of white silk, and its head surmounted by a living flower whose twelve tentacles of purest white fall behind in a graceful curve.

REVIEW ARTICLE

The pathogenesis of cancer metastasis

George Poste

Cancer Biology Program, National Cancer Institute, Frederick Cancer Research Center, Frederick, Maryland 21701

Metastases do not result from random survival of cells released from the primary tumour but from the selective growth of specialised subpopulations of highly metastatic cells endowed with specific properties that befit them to complete each step of the metastatic process.

UNDERSTANDING how malignant tumour cells are able to spread from the primary tumour to form secondary tumours (metastases) at other sites in the body is one of the major goals of cancer research. Despite advances in surgical technique and the development of aggressive adjuvant therapies for treatment of primary neoplasms, most deaths in cancer patients are caused by metastases. Research done in many laboratories in the last few years has provided important new information about basic events in the pathogenesis of metastasis and the identity of the tumour cells responsible for this fatal disease. A number of these observations challenge long held views and raise serious doubts about the adequacy of certain experimental approaches used to date to study the malignant cell. This article reviews some of these findings and their implications for the experimental analysis of the malignant phenotype and the development of agents for treatment of metastatic disease.

The metastatic process

A metastasis is a neoplastic lesion that arises from another cancer with which it is no longer in contiguity. The ability to produce metastases is a property of malignant tumour cells. Malignancy is not a characteristic shared by all tumour cells and cells that lack the ability to invade and metastasise are termed benign. This classification may seem too obvious for inclusion in a review article on metastasis. However, the most cursory examination of the literature reveals that the term 'malignant' is being used increasingly, albeit incorrectly, as a synonym for 'neoplastic' or 'tumourigenic'. It is also common to see publications that erroneously refer to '*malignant* transformation' of cells *in vitro*. In far too many instances this description is based on inadequate criteria such as changes in cell growth *in vitro* or biochemical alterations and experiments to determine whether such cells can cause tumours *in vivo* (that is, neoplastic transformation) yet alone produce metastases (that is, malignant transformation) have not been done. In this article the term 'malignant' refers only to cells that are capable of producing metastases.

The process of metastasis involves a series of sequential steps[1–3] in which malignant cells are released from the primary tumour and disseminate to distant sites where they proliferate to form new tumour foci (Fig. 1). Metastasis begins with the local invasion of the surrounding host tissue by cells from the primary tumour, either singly, or as cell clumps, or as large multicellular tongues[1]. It is not known exactly how malignant cells invade host tissues. Active and/or passive movements of tumour cells into host tissues are probably important[1]. The ability of some malignant cells to release tissue-destructive enzymes, particularly lysosomal hydrolases and collagenolytic enzymes, has also attracted attention as a possible factor in promoting tumour invasion[6–12]. However, as with virtually all aspects of tumour biology, generalisation is difficult and malignant cell lines exhibit a broad range of tissue digestive capacities[6–10].

In certain neoplasms, distant tumour foci are established by a direct spread of cells from the primary lesion along preformed mechanical pathways such as fascia planes and nerve sheaths[2,12]. Similarly, for tumours growing in major body cavities, shedding of cells from the primary lesion can produce secondary growths by seeding of cells onto the mucosal and/or serosal surfaces of other organs[12].

The more common, and most important, route of tumour spread involves invasion and penetration of tumour cells into blood vessels and/or lymphatics, with their subsequent dissemination to distant organs in the blood or lymph. Lymphatics and small, thin-walled venules offer relatively little mechanical resistance to penetration by tumour cells[2–5]. In contrast, arteries and arterioles are rarely invaded[5]. Blood vessels within tumours also offer malignant cells a port of entry into the circulation. Ultrastructural studies indicate that the endothelium of tumour-associated vessels is often defective and such vessels may be particularly susceptible to penetration by tumour cells[13]. Zones of reduced oxygenation[14] and overt necrosis[3,9,12] are common in tumours and the blood vessels in such regions show structural alterations (defects) that could facilitate invasion by tumour cells.

Some of the clinical literature still pays homage to the view that carcinomas tend to spread via lymphatics, whereas malignant tumours of mesenchymal origin spread via the blood system. There is now substantial evidence that malignant cells can pass freely between lymphatics and blood vessels[2,5]. The belief that particular tumours spread exclusively via one or other pathways is a misleading oversimplification, which does not offer a reliable basis for predicting either the distribution of metastases or the choice of therapy[4].

Following penetration of blood vessels, tumour cells are either carried away passively in the bloodstream or remain at the site of vessel invasion where they proliferate and continue to shed emboli into the circulation[2]. Shedding of emboli is exacerbated by intermittent changes in venous pressure, by turbulent alterations in blood flow and by movements or manipulation of the neoplasm during diagnostic tests or surgery[15].

The distribution of metastases

The presence of tumour cells in the circulation is necessary, but certainly not sufficient, to produce metastasis[2–5,15]. As discussed later, most tumour cells that enter the circulation do not survive to complete the process.

Knowledge of the expected tissue distribution of metastases arising from primary tumours in different anatomical locations is important to the clinician who must monitor the progress of a cancer patient and plan appropriate therapy. In man, this information has come from descriptive observation of the distribution of metastases arising from particular types of tumours. More accurate information on the behaviour of circulating tumour cells has been obtained in experimental animals by studying the distribution and fate of radiolabelled tumour cells[2].

Metastases

Fig. 1 Schematic illustration of the major steps in the pathogenesis of metastasis. Initial neoplastic transformation of susceptible cells gives rise to a small population of tumour cells. Vascularisation of this early neoplastic lesion allows further proliferation of tumour cells and enlargement of the primary tumour. Malignant cells within the primary tumour next begin to invade the surrounding host tissue(s). Entry of invading tumour cells into lymphatics or blood vessels serves to transport them to distant sites in the body where they lodge and arrest in the capillary beds of various organs. For illustrative purposes this figure depicts arrest of malignant cells in the lung capillary bed. The arrested cells then exit from capillaries into the surrounding lung parenchyma where, subject to provision of a suitable environment, they proliferate to form metastases. A more detailed discussion of each of these steps is given in the text. (Figure reproduced with permission from ref. 103).

Some degree of nonspecific trapping and arrest of circulating tumour cells in the microcirculation occurs simply as a result of mechanical factors. The size and deformability of tumour cells, the diameter and distensibility of capillaries and the interaction of tumour cells with each other and with circulating host cells to create multicellular emboli are all relevant in this context[2-4,10].

Although mechanical factors undoubtedly exert some effect on the distribution and viability of circulating tumour cells, it is now clear that mechanical factors alone are not sufficient to explain the site(s) of tumour cell arrest and metastasis formation in all human and animal tumours. Clinical observations in man suggest that certain tumours consistently metastasise to particular organs[2,12,16-18]. Non-random patterns of tumour cell arrest and subsequent metastasis formation have also been described in a variety of animal tumour systems[19-26]. Also, experimental studies in which radiolabelled tumour cells are introduced into the circulation have shown that in many instances circulating cells arrest in a wide variety of organs but metastases occur only in certain organs[2,3]. Why some organs support metastatic growth, while others that receive viable tumour cells do not, remains unknown.

Recent evidence indicates that the properties of circulating tumour cells can affect their arrest pattern. A remarkable demonstration of the ability of tumour cells to arrest and grow preferentially in particular organs is provided by experiments showing that animal tumour cells which ordinarily arrest in the lung also localise and grow in pieces of lung implanted subcutaneously (refs 24, 27 and I. R. Hart, unpublished data). In contrast, tumour growth does not occur in subcutaneous implants of other organs. Comparable findings have been obtained in experiments in which the melanoma cells shed from pulmonary metastases in one animal were found to localise preferentially in the lung of non-tumour bearing parabiotic animals[28].

Equally dramatic evidence of the influence of tumour cell properties on the arrest pattern of circulating cells has come from recent work on the experimental manipulation of plasma membrane composition in B16 melanoma sublines of differing metastatic potential[29]. In these experiments, plasma membrane components were transferred between different sublines by taking advantage of the fact that B16 melanoma cells growing *in vitro* and *in vivo* spontaneously shed closed vesicles of intact plasma membrane which can be collected and fused with other cells using polyethylene glycol. Membrane vesicles from the B16–F10 subline, which has a high capacity for lung colonisation, were fused with B16–F1 cells, which produce few pulmonary metastases. When the vesicle-modified cells were injected intravenously into C57BL/6 mice they were found to arrest in the lung capillary bed in significantly greater numbers in the lung capillary bed than untreated B16–F1 cells (Fig. 2). Equally important, increased cell arrest resulted in increased production of pulmonary metastases[29] (Table 1). The possibility that the increased arrest of vesicle-modified B16–F1 cells in the lung was due simply to increased cell volume produced by vesicle uptake was excluded by showing that the volume of vesicle-treated cells (determined from cells isolated by centrifugal elutriation) did not differ significantly from control B16–F1 cells[29].

In related experiments, lymphocyte-resistant sublines of B16–F1 were rendered susceptible to *in vitro* killing by cytotoxic lymphocytes by treatment with vesicles from lymphocyte-sensitive B16 sublines plus polyethylene glycol[29]. Since lymphocyte-mediated cytolysis occurs only when the target antigen resides within the plasma membrane[30-32], this experiment also shows that the vesicles fuse with the cellular plasma membrane and are not merely adsorbed to the cell surface.

The effect of B16–F10 vesicles in modifying the arrest of B16–F1 cells was highly specific. Vesicles from B16–F10$^{\text{lr}}$ cells (a variant of the B16–F10 subline that is resistant to killing by syngeneic immune lymphocytes, but which resembles B16–F1 in its arrest and metastatic behaviour) had no effect on the arrest of B16–F1 cells (Fig. 2). Interestingly, fusion of B16–F1 vesicles with B16–F10 cells did not alter the arrest or metastatic behaviour of these cells (Fig. 2) but this may have been because the vesicles were not introduced in sufficient amounts.

Studies using B16–F1 vesicles surface-labelled with ^{125}I or ferritin revealed that vesicle components persist in the plasma membrane of B16–F10 acceptor cells for only 18–24 hours[33].

How then does vesicle treatment enhance metastasis formation when proliferation of extravasated cells to form metastases does not begin until 1–2 days after injection[3,29] when vesicle components are no longer present? Other studies have shown that B16 cells invade the blood vessel wall within 2–4 hours after their arrest[33]. Once within the vessel wall, the tumour cells are less susceptible to damage by haemodynamic forces or circulating host cells and therefore have a greater opportunity of continuing the process of metastasis. Thus, by simply increasing the efficiency of cell arrest and invasion in the lung capillary bed, vesicle-induced modification of B16–F1 cells would increase the likelihood of metastasis formation even though vesicle components *per se* will make no direct contribution to any events occurring 24 hours after initial cell arrest.

Ultrastructural studies indicate that tumour cells adhere to the endothelium and also to the underlying basement membrane[2,13]. Recent studies by one of us (G.P.) suggest that it may be profitable to concentrate further studies on the subendothelial basement membrane of blood vessels since it seems to offer a better substrate for adhesion of malignant tumour cells than does the endothelium (Table 2). Also, tumour cells from clones of a murine fibrosarcoma with high metastatic potential adhere to the endothelial basement membrane more efficiently than clones of low metastatic potential (Table 2).

Following arrest and implantation in the vessel wall, tumour cells must exit from the vessel into the surrounding tissue(s). Extravasation of malignant cells is believed to involve mechanisms similar to those responsible for the initial invasion of blood vessels. Recent observations showing that spontaneously metastatic B16 melanoma sublines produce high levels of type IV collagenase[34] may be particularly significant in this context since type IV collagen is the predominant form of collagen in the basement membrane of capillaries[34].

Successful extravasation and limited proliferation of malignant cells creates small colonies of tumour cells, so called micrometastases, which at first surround blood vessels[35]. Further growth of these lesions to form macroscopic metastases of clinical importance requires ingrowth of new blood vessels to provide adequate nutrition to support cell proliferation. The ability of certain tumour cells to release a factor(s) that stimulates growth of new blood vessels (angiogenesis)[35] may be of advantage in this regard. It is important to note, however, that angiogenic factors are also produced by host lymphocytes and macrophages[35]. Release of angiogenic factors from these host cells as a consequence of interaction with metastatic cells, together with release of cell growth stimulating factors by host platelets, could create a situation in which the normal host homeostatic mechanisms increase the risk of metastasis.

Table 1 Formation of experimental metastases by B16 melanoma sublines and B16 sublines treated with plasma membrane vesicles

Cell type	Plasma membrane vesicles	PEG/PHA†	Average number of pulmonary metastases*
B16-F1	None	−	16±7
B16-F1	None	+	14±6
B16-F10	None	−	114±24
B16-F10	None	+	87±16
B16-F1	B16-F10	−	19±8
B16-F1	B16-F10	+	44±11
B16-F10	B16-F1	−	103±16
B16-F10	B16-F1	+	94±19
B16-F1	B16-F1	+	11±6
B16-F10	B16-F10	+	91±15

The B16 mouse melanoma cell sublines were incubated with purified preparations of plasma membrane vesicles from the indicated donor cells in the presence (+) or absence (−) of PEG and PHA for $\frac{1}{2}$ h at 37 °C as described in Fig. 2. Control cell populations which were not treated with plasma membrane vesicles were incubated in serum-free Dulbecco's modified Eagle's medium for $\frac{1}{2}$ h at 37 °C. Vesicle-treated and control cell populations were then tested for their ability to form experimental metastases after i.v. injection into 10-week-old C57BL/6 mice (5×10^4 cells per animal) as described in the legend to Fig. 2. Formation of experimental metastases was measured 18 days after injection of cells.

† PEG = polyethylene glycol; PHA = phytohaemagglutinin.

* Mean values (±s.d.) derived from measurements on 20 mice per group in two separate experiments. (Table derived from data published in ref. 29).

The immune response and metastasis

Throughout the metastatic process, malignant cells are subject to attack by host defence systems, which can be immune[36,37] or nonimmune[38] in nature. Despite an enormous effort to define the role of immune mechanisms in the recognition and destruction of tumour cells, their contribution remains unclear, and convincing evidence that they influence the outcome of neoplastic disease in man is still lacking.

The classic 'immune surveillance' theory[39] attributes host resistance to tumours to the destruction of susceptible tumour cells by mature immune T lymphocytes. This hypothesis, although widely accepted at first, has come under increasing criticism in recent years. The following findings have been cited as evidence against a central role for host immunity in surveillance against neoplastic cells: the incidence of spontaneous tumours in T cell-deficient nude mice is no higher than in immunocompetent animals; most tumours that metastasise in normal immunocompetent animals fail to do so in nude mice; some murine melanoma cells that are resistant to killing by T lymphocytes are less metastatic than cells that are susceptible to killing by T cells; and tumour growth rate in immunologically privileged sites is no faster, and often slower, than that of neoplasms in immunologically exposed sites (see refs 2, 40–44). Also, spontaneous tumours in both man and animals frequently lack detectable antigenic alterations[45,46] and might thus avoid recognition by the immune system. This conclusion comes, however, from experiments designed to detect transplantation resistance and other immune responses involving T cells. The possibility that tumour cells express antigenic or other surface changes recognised by other host defence cells such as natural killer (NK) cells or macrophages still has to be tested (see below).

Experimental studies on the role of host immunity in cancer metastasis have yielded contradictory results. In many transplantable tumour systems, depression of host immunity increases the incidence of experimental and spontaneous metastasis (see ref. 47); in other tumour systems, depression of immunologic reactivity decreases, or even prevents, metastasis[48–51] or has no influence on the growth of a local or disseminated tumour[52]. The basis for these discrepancies could be that the studies were carried out with tumours of various histologic types, of different aetiologies, and induced in different species. We have attempted to minimise these variables by testing three C3H fibrosarcomas with different degrees of immunogenicity for their metastatic activity in immunosuppressed normal, sham-suppressed and immunologically reconstituted syngeneic mice[52]. The highly immunogenic fibrosarcoma formed more pulmonary tumour colonies in immunosuppressed mice than in normal, sham-suppressed (sham-thymectomy and 450R) or reconstituted animals (thymectomy, X-ray irradiation, plus 10^7 normal syngeneic lymphocytes intravenously). A fibrosarcoma of intermediate immunogenicity also formed more pulmonary metastases in immunosuppressed recipients, but this increase could not be reversed by reconstitution with 10^7 normal lymphocytes. In contrast, the least immunogenic tumour formed fewer pulmonary tumour colonies in immunosuppressed mice than in normal, sham-suppressed or reconstituted mice. Thus, even in these relatively uniform conditions, the influence of the immune system on experimental cancer metastasis varied for different tumours. These data also show that tumour immunogenicity is an important factor in the relationship between host immunity and tumour dissemination[52].

Table 2 Adhesion of non-neoplastic cells and metastatic tumour cell variants to endothelial cells and subendothelial basement membrane

Cell	Metastatic potential*	% Cell adhesion‡ Intact endothelium	Subendothelial basement membrane
C57BL/6 mouse embryo cells	None	35.6±1.4	30.2±1.2
B16-F1 melanoma	Low	39.2±1.7	46.4±1.4
B16-F10 melanoma	High	33.4±0.9	69.7±1.5
B16-F1-BV8 melanoma†	High	36.1±1.3	83.7±2.3

UV-2237 fibrosarcoma, clone 39	High	45.2±1.8	65.8±1.7
UV-2237 fibrosarcoma, clone 25	High	37.4±1.3	80.4±1.5

Actively growing monolayer cultures of the indicated cell types were labelled with ^{125}I-IUdR as described in the legend to Fig. 2. Aliquots containing 2.5×10^4 radiolabelled cells were then plated onto the surface of 1 cm^2 segments of human umbilical vein in 0.1 ml Dulbecco's modified Eagle's medium containing 10% calf serum. The radioactivity present in five representative inocula of each cell type was measured in a Packard gamma counter. After addition of radiolabelled cells the blood vessel segments were incubated for 1 h at 37 °C. The culture medium plus non-attached cells was then aspirated and the surface of the blood vessel was washed twice with prewarmed Hanks' balanced saline solution (HBSS). The amount of radioactivity associated with the blood vessel segments was then measured and expressed as a percentage of the total radioactivity in the original inoculum. In assaying cell adhesion to intact endothelium the structural integrity of the endothelium was confirmed by scanning electron microscopy. Vessels showing partial detachment of endothelial cells or regions of complete loss of endothelial cells were excluded from the adhesion assay. For assays of cell adhesion to the subendothelial basement membrane, a balloon catheter was used to remove the majority of endothelial cells after which the vessel was treated with 0.5% EDTA to remove any remaining endothelial cells. Complete removal of endothelial cells was then confirmed by scanning electronmicroscopy.

* Ability to form experimental pulmonary metastases after i.v. injection of 1×10^5 cells. The classification refers to median number of experimental metastases produced in 10 animals[70,71]: low (1–15); medium (30–50) and high (>100).

† A variant isolated from the B16-F1 subline by *in vitro* selection for enhanced ability to invade the wall of blood vessels maintained *in vitro* in a perfusion culture system[78].

‡ Mean±s.e.m.

The existence of a system of natural host defence against tumour cells mediated by natural killer (NK) cells[42] offers a possible alternative mechanism for cell-mediated surveillance against circulating neoplastic cells. The role of NK cells, and also activated or armed macrophages[53], in limiting tumour growth and metastatic spread, as well as the related questions of amplifying NK- and macrophage-mediated destruction of tumour cells[54,55] as methods for treating micrometastases are presently being studied in many laboratories and the outcome of this work is awaited with considerable interest.

Metastasis as a selection process and variation in the metastatic capabilities of tumour cells

Metastasis is a highly selective process. The malignant cells that complete all of the steps described in the previous section and establish metastases have survived a demanding sequence of hostile events which destroy the majority of tumour cells[2–4]. For example, only a small proportion of the total cells from the primary tumour may gain access to the circulation and of these as few as 0.1% may survive the trauma of dissemination and arrest[2]. Surviving cells suffer further loss during extravasation and the viability of extravasated cells, in turn, may depend on the availability of appropriate nutrients and escape from destruction by host defence systems.

Recognition that only very few tumour cells survive to develop into metastases raises the important question of whether survival is random or non-random. Random survival would mean that the primary tumour is populated by cells of equal metastatic potential, any one of which could give rise to a metastasis. The alternative possibility is that metastasis is not random, but involves the survival of specialised tumour cells endowed with specific properties that befit them to complete each step in the metastatic process. In this case, the primary tumour would contain subpopulations of cells of differing metastatic potential, including cells with little or no capacity to metastasise.

The possibility that cells with high metastatic potential can be isolated from a heterogeneous parental tumour by selection procedures was first suggested in 1939 by Koch who isolated a highly metastatic subline from the Ehrlich carcinoma tumour by serially transplanting lymph node metastases[56]. In 1955, Eva Klein demonstrated that gradual conversion of some solid murine neoplasms into ascites variants was due to the selective overgrowth of a small number of cells which differed from the parental population in their ability to proliferate in the peritoneal cavity and metastasise to the lungs[57]. Since the change was stable and heritable, Klein concluded that the gradual conversion of the solid tumour to the ascites form involved mutation/selection and not adaptation. Further evidence of heterogeneity in the metastatic potential of tumour cells has come from more recent experiments in which selective harvesting of cells from metastases during successive passages of tumour cells *in vivo* has yielded cell populations with a greater metastatic potential than cells from the original cell population[19,22,58–70]. In this type of *in vivo* selection the isolated cell populations are not cloned, and the enhanced metastatic potential detected in the population as a whole is due to enrichment of the proportion of highly metastatic cells in the population at each successive passage.

Definitive evidence that malignant primary tumours contain subpopulations of cells with differing metastatic capabilities was obtained in 1977 by Fidler and Kripke[70] using the B16 melanoma syngeneic to the C57BL/6 mouse. To investigate whether primary tumours contained cells of differing, or uniform, metastatic potential they prepared a cell suspension from a subcutaneous primary tumour and divided it into two aliquots. One part was immediately assayed for its ability to form experimental pulmonary metastases following intravenous injection (a procedure for assaying cellular metastatic ability which has been validated elsewhere[71]). From the second part of the original suspension, 17 clones were isolated and their progeny tested for their ability to produce experimental metastases. If the tumour was populated by cells of uniform metastatic potential, then the cloned sublines should each produce the same number of metastases as the uncloned parental population. This was not the case. The original uncloned parental tumour cell population produced similar numbers of metastases in different animals but the cloned sublines differed markedly in their metastatic potential (Fig. 3). Although the number of metastases produced by any given clone was constant, individual clones showed wide variation in their metastatic potential. Control subcloning experiments demonstrated that the cloning process was not responsible for the variability[70]. These experiments thus suggest that the parent B16 tumour is heterogeneous and that highly metastatic tumour cell variants preexist in the parental population[70].

To exclude the possibility that the metastatic heterogeneity found in B16 melanoma clones might have been introduced as a

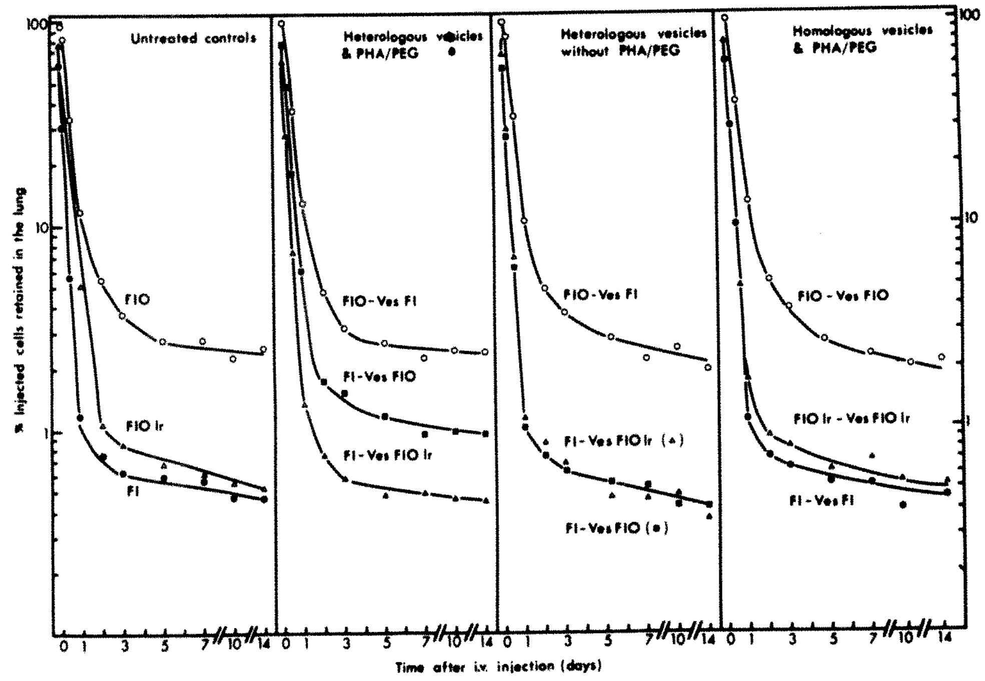

Fig. 2 Lung arrest and retention of ^{125}I-IUdR labelled B16 melanoma sublines and B16 sublines treated with plasma membrane vesicles after i.v. injection into C57BL/6 mice. Plasma membrane vesicles (Ves-F1; Ves-F10$^{\mathrm{lr}}$; Ves-F10) were purified from the culture medium of actively growing roller bottle cultures of the various B16 sublines and were purified as described elsewhere[29]. ^{125}I-IUdR-prelabelled cells from the indicated B16 sublines (F1, low lung metastasis; F10, high lung metastasis, F10$^{\mathrm{lr}}$, lymphocyte-resistant variant of F10 with low metastatic capacity) were incubated in suspension with homologous or heterologous vesicles (300–400 μg protein per 10^7 cells) in serum-free Eagles minimum essential medium (MEM) with or without 50 μg ml^{-1} PHA-P and PEG 6000 as described elsewhere[29]. Control cells were incubated without vesicles in serum-free MEM for the same period. Vesicle-treated and control cells were then washed three times with prewarmed Hanks' balanced saline solution (HBSS) and incubated for 10 min at 37 °C in 0.2% EDTA to separate multicellular clumps into single cells. Since cell size can influence cell arrest in the microcirculation, vesicle-treated and control cells injected into animals (see below) were subjected to density gradient centrifugation and centrifugal elutriation to obtain cell fractions of similar size and density[29]. Aliquots of 1×10^5 viable, radiolabelled cells with a modal volume in the range $1.4–1.6 \times 10^3$ μm^3 were then injected as a single cell suspension in 0.2 ml HBSS into the tail vein of unanaesthetised C57BL/6 mice. The radioactivity present in five representative inocula was monitored for each cell preparation in a gamma counter. Lungs were collected from injected mice at intervals from 5 min to 14 days after injection and placed in vials containing 70% ethanol. The ethanol was changed daily for 3 days to remove alcohol-soluble radioactivity. The remaining lung-associated radioactivity represents radioactivity incorporated into the DNA of tumour cells that were viable at the time the animals were killed[104]. Lung-associated radioactivity at the indicated times after injection is expressed as a percentage of the injected cells retained in the lung. Each point represents a mean value derived from measurements of five separate animals. The arrest kinetics of ^{125}I-IUdR-labelled F1, F10 and F10$^{\mathrm{lr}}$ cells treated with PHA/PEG but not exposed to vesicles did not differ from that shown in the left-hand panel for untreated control cells from these sublines. Figure constructed from data given in ref. 29.

result of the lengthy *in vivo* and *in vitro* cultivation that this tumour has undergone since its isolation in 1954, Kripke and Fidler repeated the same experiment with a newly induced primary tumour and tested the metastatic potential of cells isolated from this tumour after only 6 passages *in vitro*. The results obtained with this tumour, a UV-induced fibrosarcoma (UV-2237) of a C3H mouse, were similar to those obtained with the B16 melanoma. Similarly, marked heterogeneity in metastatic potential has now been demonstrated in cloned populations isolated from a murine mammary tumour[72], a murine MCA-induced fibrosarcoma[73], a murine sarcoma virus-transformed fibrosarcoma[26] and a transformed rat liver epitheloid cell line[74]. More recently, we have shown that whereas clones isolated from the primary tumour show widely differing metastatic abilities, cloned sublines isolated from individual metastases exhibit a much more uniform metastatic potential. This suggests that metastases, in contrast to the primary tumour, are more homogeneous and populated by cells with similar metastatic capabilities (Fig. 3).

Metastatic and non-metastatic tumour cell variants derived from the same parent tumour cell population have also been isolated using *in vitro* selection methods in which cell populations are selected for expression (or failure to express), a property considered of possible importance in one or more steps in the metastatic process. The metastatic behaviour of such isolated cells is then assayed *in vivo* to determine whether the particular selection has enriched the population for cells with increased or decreased metastatic capacity. Selection *in vitro* for detachment from a monolayer[75], resistance to lysis by lymphocytes[76], resistance to lectin-mediated toxicity[77], attachment to collagen[58] and ability to invade various tissues maintained in organ culture[78] have now been used successfully to isolate tumour cell lines with increased or decreased metastatic capabilities.

Collectively, this large body of evidence indicates that malignant tumours are not uniform entities populated by cells of equal metastatic potential. Rather, primary tumours are populated by subpopulations of cells of widely differing metastatic potential. This conclusion supports the proposal made by Nowell[79] that during tumour progression variant cells arise which are subject to host selective pressures that favour the survival of variants with increased malignant capacity. Regardless of whether neoplasms are monoclonal or multiclonal in origin[79,80], by the time they can be diagnosed clinically they could be heterogeneous and contain subpopulations of cells with a wide range of phenotypic characteristics. Recent studies by one of us (I.J.F.) using mouse fibroblasts transformed *in vitro* by cloned stocks of murine sarcoma virus have shown that extensive heterogeneity in metastatic potential is present in subclones derived from the original transformed cells as little as 28 days after the initial transformation.

Heterogeneity in the metastatic potential of cells in the primary tumour is perhaps not unexpected. Cells populating both human and animal neoplasms are known to be heterogeneous with respect to their immunogenicity[83], antigenic properties[82–84], growth rate[85], metabolic characteristics[86], hormone receptors[87], pigment production[88], radiosensitivity[89] and susceptibility to cytotoxic drugs[90–92]. Of even more interest in the context of the present discussion are recent observations showing that tumour cells in primary and metastatic lesions differ in their antigenic properties[93], biochemical characteristics[94] and response to cytotoxic drugs[61,95–97].

Implications

The presence within the primary tumour of subpopulations of cells with differing metastatic capabilities has profound implications for the way in which research is done to identify the cellular properties responsible for metastasis. Hitherto, the general experimental approach to this problem has been to study cell populations isolated at random from the primary tumour and to assume that properties detected in these cells are also expressed by cells that give rise to metastases. The demonstration of metastatic heterogeneity in the cells of the primary tumour indicates that this assumption is not valid. Experimental efforts to identify features unique to metastatic subpopulations will require isolation of such subpopulations and comparison with nonmetastatic (but tumorigenic) subpopulations of cells from the same parent tumour. Continued efforts to study the properties of malignant cells using unselected heterogeneous cell populations will probably be of little value since the proportion of nonmetastatic or poorly metastatic cells may be sufficiently high to mask properties peculiar to small subpopulation(s) of highly metastatic cells. Moreover, studies that utilise tumour cells isolated from tumours whose detailed origins are not known or tumours propagated by serial transfer intraperitoneally may be unproductive in that the former may not be syngeneic to the recipient animals while the latter may represent a selected subpopulation of cells since growth intraperitoneally has been shown to be selective[57].

The existence of specialised subpopulations of cells with high metastatic potential has equally far reaching consequences for the testing of potential agents for treating metastatic disease. Both human and animal neoplasms contain subpopulations of cells with differing sensitivities to cytotoxic drugs[90–92]. Differences in the response of primary and metastatic lesions to therapeutic agents is well documented in clinical practice[98] and metastatic cells showing increased resistance to chemotherapeutic agents have been selected in experimental animal tumours[61]. As pointed out recently by Schabel *et al.*[98], most of the methods presently used to define the drug sensitivity of experimental animal tumours might be misleading since they are based on the belief that transplantable tumours are homogeneous, that is, uniform entities. Assays of the antitumour activities of therapeutic agents that rely on partial regression of the primary tumour may be inadequate for screening agents for

Fig. 3 Schematic illustration of experiments demonstrating heterogeneity in the metastatic capabilities of clones derived from cells in a parental murine tumour[70] and the relative homogeneity of the metastatic potential in clones derived from cells isolated from a pulmonary metastasis (G.P. and I.J.F., unpublished data). The experiment was similar in design to the classical fluctuation test devised by Luria and Delbruck to distinguish between selection and adaptation in the origin of bacterial mutants[105]. Cells isolated from the parental tumour were divided into two parts. One part (left-hand side of figure) was injected i.v. into 60 C57BL/6 mice to assay formation of experimental pulmonary metastases. The other part (central portion of the figure) was used to produce a series of clones and the progeny of each clone was injected i.v. (10 mice per clone) in an identical procedure to that of the uncloned parental tumour cells. Mice were injected i.v. with 5×10^4 viable cells and the number of lung metastases was measured 18 days later by examining the lungs with a dissecting microscope[70]. Cells of the parental population produced a median of 40 lung metastases (range 8–131 metastases). In contrast, cells of clones from the parental tumour differed markedly in their metastatic capabilities, from very low (range of median number of metastases from 7 clones = 3–20), medium (medians from 3 clones = 36–99 metastases), high (medians from 5 clones = 150–260 metastases) to very high metastatic capacity (medians from 2 clones = >500 metastases)[70]. In contrast, clones derived from cells isolated from a single pulmonary metastasis (right-hand side of figure) were of uniform metastatic potential when assayed in similar experimental conditions. This indicates that the metastatic lesion is composed of a more homogeneous cell population with a relatively uniform metastatic capability. The clones shown in the figure produced a uniformly high number of metastases. Although the number of metastases produced by cells isolated from any given metastasis is uniform, clones isolated from different metastases may differ substantially in the number of metastases they produce (G. P. and J. Doll; I. J. F., E. Gruys and M. L. Kripke, unpublished data). This reflects differences in the metastatic activities of the original tumour cell subpopulations residing within the parental tumour which give rise to individual metastases[70].

their antimetastatic activity. Assays in which a drug, or combination of drugs, are found to limit growth of the primary tumour to 50% of that in untreated controls may merely reveal the presence of a subpopulation(s) of drug-sensitive cells and do not necessarily offer any insight into the pharmacologic susceptibility of the tumour cell subpopulations that will give rise to metastases. Future efforts to identify potential agents for treatment of metastases might thus more profitably adopt assays in which therapeutic agents are screened for their activity against cloned tumour cell subpopulations with defined metastatic capabilities.

Phenotypic heterogeneity is not only a problem for the chemotherapist. Immunologic heterogeneity among tumour cells[82–84, 93, 99] poses equally serious problems for efforts to treat neoplastic disease by specific immunotherapy[100]. For example, analysis of a number of AKR mouse lymphomas of recent origin has shown that these tumours are immunologically polyclonal, consisting of a numerically dominant subpopulation and several distinct minor subpopulations that comprise less than 3% of the tumour. Attempts to induce tumour rejection by immunising tumour-bearing animals using unfractionated thymoma cells were unsuccessful since effective immunisation occurred only against the dominant clone and the minor subclones did not offer a sufficient immunologic mass to stimulate the immune response[101]. Immune rejection of the dominant clone merely permits the minor subpopulations to proliferate and become dominant. This situation is analogous to the well documented problem of drug-resistance in cancer chemotherapy where resistant variants preexist within the parental tumour population, albeit as a minor subpopulation, but following destruction of the original dominant drug-sensitive population(s) they proliferate unchecked[102].

Recognition that primary malignant tumours are not populated by cells of equal metastatic potential, but contain subpopulations of cells with widely differing metastatic capabilities, calls for critical reappraisal of the adequacy of many of the experimental systems presently used in studying 'malignancy' and in screening agents for treating metastatic disease. Experimental systems that fail to take account of the heterogeneity of metastatic potential of neoplasms may prove to be less successful in providing insight into the basic mechanisms involved in metastasis than systems that embrace this concept. We thus consider the isolation and characterisation of tumour cell variants of defined metastatic potential from human and animal neoplasms to be of major importance for future progress in metastasis research.

The search for a property uniform to all metastatic cells may be unproductive. Work carried out with isolated variant tumour cell lines must consider that the development of metastases is dependent on an interplay between host factors and the intrinsic properties of the tumour cells. To establish metastases, tumour cells must complete *all* steps involved in the metastatic process. Enhanced performance of a tumour cell in one step of the process cannot compensate for an inability to complete a subsequent step. The failure of most tumour cells to produce metastases need not be due to a single, common factor. Interruption of the metastatic sequence at any step in the process will prevent the production of clinical metastasis. On a more optimistic note, the increasing availability of tumour cell populations with differing metastatic capabilities should facilitate experimental efforts to identify the properties which enable malignant cells to metastasise. With the availability of this knowledge it might then be possible to design more effective procedures for the treatment of this catastrophic disease.

New results from optical polarimetry of Saturn's rings

Paul E. Johnson, James C. Kemp, Randall King, Timothy E. Parker & Mark S. Barbour

Department of Physics, University of Oregon, Eugene, Oregon 97403

Linear polarimetry of Saturn's rings, obtained through the period of the 1979 opposition, is presented. The polarisation clearly correlates in direction with the plane containing the Sun, planet and Earth, but not the ring plane. The results are consistent with local scattering on the surface of individual ring bodies, covered with frost.

SATURN'S rings have intriguing and rather special optical properties. The rings undergo a sharp surge in brightness during a narrow phase interval around opposition[1], when the Sun, Earth, and Saturn are aligned. Water ice in some form is present on the rings and apparently controls their optical behaviour[2,3]. The geometrical arrangement of the ring particles—either a single monolayer of bodies or a thicker (low-density) disk—has long been a subject of speculation[4]. The typical size of a ring body is poorly known, with diameter estimates ranging from 1 cm to 1 km (ref. 5). One Earth-based tool which is useful for probing the nature of the rings is the measurement of the polarisation of light reflected from the rings.

Polarisation theory

The laboratory investigations of Lyot[6], Dollfus[6,7], and others have provided much information on the polarisation of light reflected from terrestrial and lunar materials. These studies have shown that the variation of polarisation with phase angle (angle between the incident and emergent light rays) is diagnostic of both the bulk properties and the texture of the surface material.

The polarisation of light reflected from a flat, polished surface is polarised so that the electric vector (**E** vector) of the polarised component is parallel to that surface, in compliance with Fresnel's laws of reflection. Typical Solar System bodies, however, tend to be covered by either a particulate or rough and pitted surface, presenting an ill-defined surface boundary. The light scattered from such a surface is found to be polarised with the electric vector lying either in the scattering plane (termed negative polarisation) or perpendicular to that plane (positive polarisation), depending on the phase angle and other parameters. The so-called negative branch is confined to a narrow interval around zero phase, that is, around opposition.

On the grounds of general symmetry, we might expect two types of contributions to the polarisation of Saturn's rings, one correlated with the ring plane, the other with the scattering plane (the plane including the Sun, planet and Earth). The idea of a ring-plane polarisation is particularly attractive because Saturn's rings are extremely thin and flat within telescopic resolvability; and physical mechanisms can easily be cited for such an effect. One characteristic of this type of polarisation, correlated in direction (position angle) with the ring plane, is that it should not vanish at precise opposition. It would be seen most clearly at opposition, as other polarisation effects correlated only with the scattering plane would then vanish, the scattering plane being undefined at zero phase. We will show that the absence of correlation with the ring plane means that any polarising mechanism related to the ring plane, as such, must be ineffective.

Only a few investigations of the linear polarisation of the light reflected by Saturn's rings have been published since Lyot's original discovery in 1923 [6–10]. Lyot[6] attempted to explain the polarisation of the rings as being due to two or three independent mechanisms: (1) direct scattering of sunlight by individual ring bodies; (2) scattering of light from Saturn's disk, by the rings; and (3) multiple scattering between aligned ring bodies. Mechanisms (2) and (3) would produce a polarisation of the type with a position angle related to the ring plane. Dollfus[9] finds a component in the polarisation of the B ring with a position angle directed either radially or tangentially, relative to the centre of Saturn, unexpectedly varying in time (on a time scale as short as several days). He reports that this rapidly variable component can be as large as 0.2%. Our measurements, with those in ref. 8, show no evidence for such a component. Rather, we find that polarisation varies smoothly with phase angle.

Observations

Figures 1 and 2 show the linear polarimetry of Saturn's rings obtained between December 1978 and May 1979. The data consist of two independent subsets, acquired at different observatories, each with a separate polarimeter and observing team. Measurements at the Pine Mountain Observatory of the University of Oregon (PMO) were made (by J.C.K., T.E.P. and M.S.B.) using the 61-cm telescope. A 41-cm telescope was used at the Kitt Peak National Observatory (KPNO) (by P.E.J. and R.K.). All PMO observations used a 7 arc s aperture, while at KPNO an 11 arc s aperture was used. Measurements were made with either a standard B filter or a yellow interference filter (V') having $\lambda_{\text{eff}} = 5{,}530$ Å and $\Delta\lambda = 700$ Å.

Both photoelastic-modulator polarimeters have been checked (in connection with other work) against both polarised and unpolarised standard stars; each has a typical[11] measured instrumental polarisation $\leq 0.01\%$. Excellent agreement between the two subsets of data (better than $\pm 0.02\%$ in ΔP for the B-filter data, and $\pm 2°$ in $\Delta\theta$) is evident in Figs 1 and 2.

All measurements were made on the east-ring ansa, such that the tip of the A ring was approximately centred in the aperture. Thus, portions of both the A and B rings were included in the aperture, with A contributing about twice as much as B to the measured flux, at this inclination of the ring plane relative to the line of sight. Sky measurements were made by offsetting the aperture to the north, by about one aperture diameter, around the arc of a circle centred on Saturn's disk. Even on nights of

0028–0836/80/020146—04$01.00

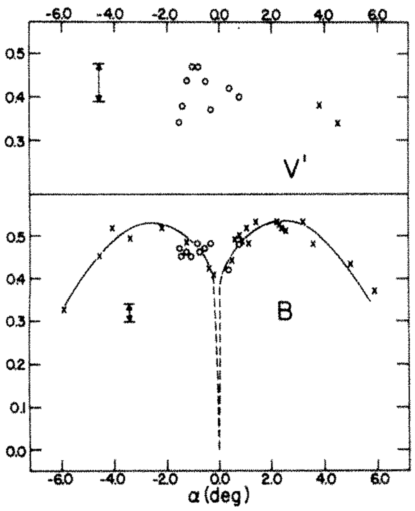

Fig. 1 Polarisation of Saturn's rings in B and V′ filters versus solar phase angle (α). ×, PMO data; O, KPNO data. Error bars at the left represent the typical error of one observation. A curve, symmetric about the origin, is hand drawn through the B-filter data. The dashed lines indicate an hypothesised polarimetric opposition effect. The position angle of polarisation always lies in the scattering plane, thus all the p values are 'negative'.

worst seeing, scattered light so measured never amounted to more than 10% of the flux on the ansa, either in terms of the polarised or total fluxes. Thus, stray light from Saturn's disk or other sources had no appreciable effect on the results.

Figures 2 and 3 show that the angle of polarisation always lies in the Sun–planet–Earth (SPE) plane. Because Saturn's orbital plane is slightly tilted out of the ecliptic plane, near opposition the SPE plane rotates by almost 180° on the plane of the sky. The polarisation follows the SPE plane, rotating also by almost 180°—see Fig. 3: this is our key result.

The tight correlation of the position angles with the position of the SPE plane, and the smoothness of our polarisation-phase curve over weeks, do not suggest any randomly varying component in the B-band polarisation as large as 0.10%. J.C.K. and Murphy[8] did not detect either azimuthal or temporal variations in the angle of polarisation around either the A or B rings to within ±4°. Comparing our measurements (at a ring tilt of −6°) with these (at a ring tilt of −26°), we also find no evidence for variation of the B-band polarisation with ring tilt, to within $\Delta p = \pm 0.1\%$, if comparison is made at the solar phase angle of 5.5°. The polarisation seems to depend only on the SPE (solar-phase) angle, at least in blue light.

Discussion

Because the angle of polarisation coincides strictly with the SPE plane, the polarisation seems to be mainly generated by intraparticle scattering (local scattering on individual, rough-surfaced ring bodies) and not by interparticle scattering (between discrete ring bodies).

Two other proposed mechanisms for the polarisation of Saturn's rings cannot explain the position-angle variation: (1) light received from the disk of Saturn and subsequently scattered towards us by the rings, or (2) multiple scattering between ring bodies, particularly in a monolayer.

Mechanism (2) here would be analogous to the mechanism which generates the phase-independent 'limb' polarisation which occurs on Jupiter's disk[10]. In that case the polarisation arises from double scattering between aerosol particles in a horizontal thin layer in the jovian atmosphere. This effect is shown in Fig. 4.

In a monolayer, a fraction of the incident sunlight is scattered between ring bodies in paths which lie parallel to the ring plane. Light could be scattered by one ring body (O) to bodies in front of or behind O, that is, a or a'; or to bodies on either side, that is, b or b'. But scattering to bodies above or below the ring plane (as c or c' in Fig. 4) is absent. This asymmetry results in a net polarisation, even with exact back-reflection, that is, at opposition. The dominant contribution to the polarisation is from the paths from O to b and b', which involve scattering angles of the order of 90° and thus large polarisations. As the polarisation at such angles for solid bodies has a positive sign, the resulting polarisation for the monolayer would no doubt be positive, with the emergent **E** vector normal to the monolayer.

In a low-density ring (many bodies thick), light paths c and c' in Fig. 4 are not eliminated. Then the interparticle scattering will tend to be isotropic, and the process just discussed would be suppressed.

We can set an upper limit to the polarisation contributed by double scattering between ring bodies in a monolayer model by assuming the rings to be a close-packed array of spheres, appropriate for the B ring which was an optical depth close to unity[4]. We write

$$p \approx GL \qquad (1)$$

where G is the ratio of doubly-to-singly scattered light, and L is the polarisation of light reflected by an individual ring body at a scattering angle ~90°. Higher-order scattering is ignored. G can be viewed as simply that portion of the sunlight impinging on one ring body which is intercepted by a second body and which, also, can then be deflected towards the Earth without shadowing. For an isotropic scattering phase function we find:

$$G \approx a\tilde{\omega}/(4\pi d^2) \qquad (2)$$

where $\tilde{\omega}$ is the equivalent single-scattering albedo for a ring body, d is the mean length of the scattering path between two ring bodies, and a is the mean area of all other ring bodies 'seen' by both the initial scatterer and the observer, taking account of the blocking by other ring bodies. $d = D - R$, where D is the mean centre-to-centre separation of ring bodies and R is the mean ring-body radius.

For the data presented here, the rings are seen close to edge-on. For a close-packed monolayer, only the tops of the individual bodies can be seen from the Earth or the Sun. The rays involved are those striking the top or 'cap' of one sphere, then being scattered by the exposed cap of an adjacent sphere, or more precisely by half of such an exposed cap. From a careful consideration of this geometry we find that at a ring-tilt angle of

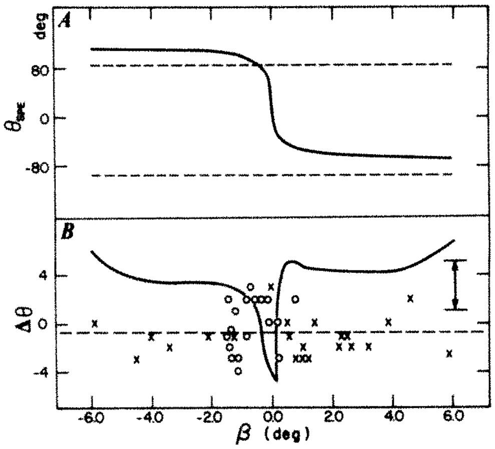

Fig. 2 *A*, The variation of the position angle of the Sun–planet–Earth plane (θ_{SPE}) with β, the angular distance of Saturn from the sub-solar point, along the ecliptic. (Note that $\beta \cong \alpha$, where α is the Sun–planet–Earth angle, except at very small α.) The dashed lines indicate the geocentric position of the major axis of the rings. *B*, The deviation of θ (the polarisation position angle) from θ_{SPE} (where $\Delta\theta = \theta - \theta_{\mathrm{SPE}}$). ×, PMO data; O, KPNO data. The solid line is the combined result of the measured mean curve (dashed line) with addition, in Stokes-vector space, of a hypothesised phase-independent polarisation of 0.08% having its **E** vector normal to the ring plane.

6°, with $\tilde{\omega} = 0.75$, the parameter G is quite small, about 0.01. This applies to the B ring. For the A ring, the ring optical depth being less by a half, the G factor would be also halved.

Thus the effect of a possible 'monolayer' constituent in our observed polarisation can be dealt with if we retain only L (the polarisation of a ring body at scattering angles ~90°) as an unknown parameter. A monolayer polarisation would be essentially phase-independent; the **E** vector would remain normal to the ring plane and would not follow the rotation of the SPE plane on the sky, as in Fig. 3. The observed angle behaviour is more consistent with a constant $\Delta\theta = 0$, that is, with the dashed line at the bottom in Fig. 2. The addition of a small monolayer effect would be to shift the curve $\Delta\theta$ from the zero line—we would find a perturbed curve $\Delta\theta(\alpha)$. Such a function is plotted (solid curve) in Fig. 2, for an arbitrary choice of $L = 8\%$. From least-squares fitting of $\Delta\theta(\alpha; L)$ to our position-angle data, we find that the 3σ upper limit for a monolayer-like polarisation is 0.03%. With $G = 0.01$ as estimated above, we deduce that the 90° polarisation by an individual ring body could not exceed 3%—if the rings were indeed a monolayer.

A similar disturbance $\Delta\theta(\alpha)$, (a variable change in position angle away from the SPE plane) would arise from a polarisation constituent due to light from Saturn's disk, rescattered to Earth by the rings. To discuss this we relax the assumption of a monolayer for the rings. Equation (1) applies, but G is now the ratio of sunlight scattered first by Saturn's disk and then by the rings, to sunlight returned directly to Earth by the rings. A fair value for G is ~0.01, as has been computed by Price and Baker[13] in another context. This polarisation would again be almost phase-independent, with the emergent **E** vector most likely normal to the ring plane. For estimating the magnitude of this effect we assume only single scattering of light by individual ring bodies; we neglect multiple light paths between discrete ring bodies. (Multiple scattering locally on the surface of a rough-surfaced ring body, however, is not ignored; that is included by specifying a value of L for a typical, macroscopic ring body.) Following equations of Cook *et al.*[14], we find that the ratio of multiply-to-singly scattered radiation from the rings, in this sense, does not exceed 0.1, for a low-density ring and a single-scattering albedo of 0.75; single scattering by the ring bodies is dominant. As for the pure monolayer effect discussed above, we are again able to place a 3-σ upper limit on the large-angle ring-body polarisation of ~3%; for a larger value, we would surely see a distortion in the $\Delta\theta$ curve.

Note that, regardless of the precise structure of the rings, our phase curves—especially of the position angle—provide an extrapolated upper limit for the polarisation, at angles of the order of 90°, for scattering from the ring bodies, namely about 3%. The small large-angle polarisation, the moderately large negative polarisation at small angles (~0.5% in the blue), and the flatness of $p(\alpha)$ near opposition, are unique. Only the published polarimetry data of a few laboratory samples are similar. They include a ground, transparent, amorphous silicate, uncontaminated by low-albedo material (contaminated silicates are not similar)[15]; and fine-grained water frost as well as freshly chipped white clay[16]. Thus the polarisation is particularly consistent with frost.

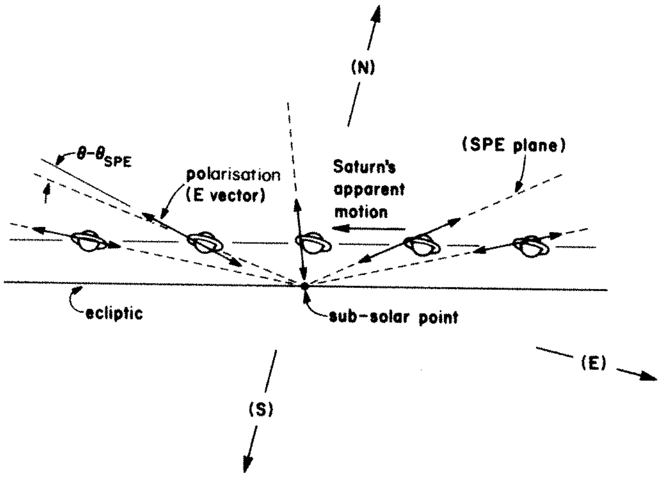

Fig. 3 A representation of the relationship between the position of Saturn's rings and the position angle of the ring polarisation. (Not drawn to scale.)

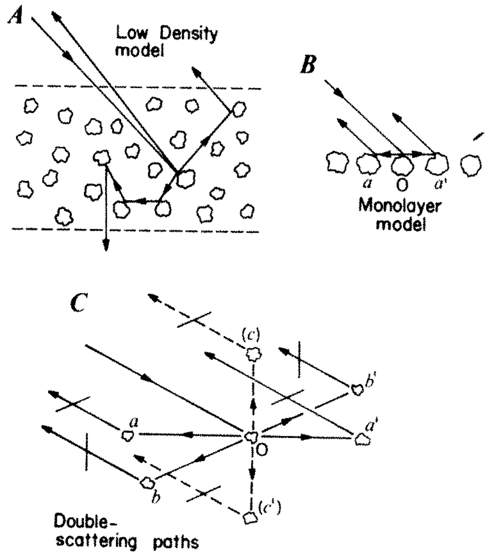

Fig. 4 The low-density and monolayer ring models showing the possible distribution of multiple scattering paths. In *C* particles *a* and *a'* are 'in front of' and 'behind' particle O, respectively. Particles *b*, *b'* are 'off to the side'; particles *c*, *c'* are 'above' and 'below' particle O respectively. In a monolayer, *c* and *c'* are absent. A monolayer viewed from the side is seen in *B*.

Both experimental evidence[7] and theoretical analysis[17] indicate that negative polarisation (**E** vector parallel to the scattering plane) cannot be generated by scattering between widely-separated particles. The polarisation phase curve of Saturn's rings is therefore apparently accounted for strictly by local scattering on individual rough-surfaced bodies, as with the Moon's polarisation; it is not controlled by effects of mutual shadowing and reflection between ring bodies.

Simple rough-surface polarisation should drop to zero at zero solar phase angle. Our phase curves, however, show only a slight trend to zero near opposition, even down to the minimum observed phase angle of 0.22°. The drop to zero must occur in a narrow 'cusp' <0.5° wide, for visible wavelengths. This very sharp opposition effect can also be seen in data for both the rings and for high-albedo laboratory samples, reported by Dollfus[16].

This behaviour agrees qualitatively with the theory of Wolff[17] for the polarisation of light reflected from rough surfaces. In his theory the small-angle polarisation is governed by double reflections between grain facets, combined with shadowing. He predicts a 'cusp' in the polarisation phase curve with a width of the order of that of the photometric ('brightening') effect at opposition. The known width of the latter is indeed <0.5° (ref. 1). We assume here that the photometric phenomenon is also due to localised scattering and shadowing on the rough surfaces of macroscopic ring bodies, rather than to mutual effects between such bodies.

Conclusion

In other astronomical contexts, for example, in B-emission stars, the presence of a disk-like structure is known or presumed to produce an optical polarisation, correlated in direction with the disk plane. In the most striking example of a disk-like structure in our Solar System, Saturn's rings, we have shown that such an effect is not readily visible. Rather, a competing effect, correlated geometrically not with the disk but with the Sun–planet–Earth plane, is dominant under all conditions, even near exact opposition, at which time the disk-like component should be most readily distinguishable. At least two mechanisms have been cited for the production of a disk-like polarisation: a monolayer effect; and the rescattering of sunlight reflected from the body of planet, by the rings. The former would operate only to the extent that the disk approximates a monolayer; but the second mechanism is surely applicable. The observed smallness of the contribution to the polarisation due to either or both of these mechanisms, $\leq 0.1\%$ in blue light, relative to the polarisation of $\sim 0.5\%$ caused by direct scattering of sunlight by the rough surfaces of individual ring bodies, has been attributed to the optical properties of the ring bodies. We conclude that the large-angle ($\sim 90°$) scattering polarisation of the ring bodies is quite small, $\ll 10\%$. This quantitative feature has evidently precluded the detection of a disk-like polarisation. Polarimetric results from Pioneer 11 will be of great interest, specifically with respect to our prediction that the large-angle polarisation of the rings—not directly measurable from Earth—must be very small.

Some investigators[14,18] have supported the hypothesis that the photometric opposition (brightening) effect is caused by shadowing within the surface microstructure of individual ring bodies. Others[19] have argued that the singular magnitude and sharpness of the effect is due mainly to mutual shadowing among the discrete ring bodies, and the opposition brightening by such a mechanism has been extensively modelled[12,19,20]. As the cusp in the $p(\alpha)$ curve (Fig. 1) is as narrow as the brightness peak, we can presume the polarimetric and photometric opposition effects to be parts of the same process; thus our results, substantiated by Dollfus' data, indirectly support the first of the two hypotheses for the brightening. If the polarisation were controlled by multiple light paths between the ring bodies, rather than by the local rough-surface texture, a ring plane-correlated polarisation would have been detected.

The polarisation phase curves for the rings are rather unusual when compared with those of other planetary objects and laboratory samples. Only a few published cases are known of laboratory samples exhibiting a strong, flat negative branch combined with a very weak positive polarisation at large angles. This may be due to the lack of laboratory data on high-albedo materials, especially frosts. More work on laboratory frosts would be of interest and should include the difficult polarimetric measurements at extremely small phase angles ($<0.5°$), so that the narrow 'cusp' can be defined.

Finally, more complex models for the rings may be necessary to account for all of the optical phenomena, including the polarisation behaviour. For example, a two-component model involving a haze layer is being considered in connection with the IR emission (R. E. Murphy, personal communication).

We thank T. Gehrels, R. Murphy, J. Pollack, M. Wolff, and B. Zellner for discussions, and A. Dollfus, W. Irvine and D. Smith for helpful comments. P.E.J. and R.K. are guest observers of the Kitt Peak National Observatory which is operated under contract with the NSF. The work was supported by the Planetary Science Division of NASA.

Note added in proof: Larry Pleskot (private communication) finds that the sharp opposition effect of Saturn's rings can be approximated in the laboratory with a fine-grained winter frost covering a macroscopically rough substrate. Indeed, one characteristic of high-albedo surfaces seems to be such an opposition effect. He concludes, as we do, that the opposition effect of Saturn's rings cannot be modelled solely on the basis of mutual shadowing of discrete ring bodies, but must include the effects of scattering on the surface of individual bodies.

U–Pb, Sm–Nd and Rb–Sr systematics of mid-ocean ridge basalt glasses

R. S. Cohen*, N. M. Evensen, P. J. Hamilton & R. K. O'Nions*

Lamont-Doherty Geological Observatory, Columbia University, Palisades, New York 10964

The measurement of Pb, Nd and Sr isotopes in basalt glasses from mid-ocean ridges reveals correlations in isotope parameters which have important implications for the differentiation history of the mantle.

THE isotopic compositions of Pb, Nd and Sr in oceanic basalts reflect the fractionation histories of U/Pb, Sm/Nd and Rb/Sr in their mantle sources, and therefore may throw light on several important problems including the differentiation of mantle material to produce continental crust, the recycling of continental material and the degree of convective mixing in the mantle. As mid-ocean ridge basalts comprise nearly 80% of the Earth's volcanic products they should convey a good impression of the isotopic characteristics of the sub-oceanic mantle. However, ocean island basalts because of their accessibility and state of preservation have attracted much more attention from isotope geochemists despite their comparatively small volume.

Early investigations of the Rb–Sr systematics of oceanic basalts established that mid-ocean ridge basalts often possess Rb/Sr ratios that are too low to generate their measured $^{87}Sr/^{86}Sr$ ratios in ~ 4.5 Gyr from a chondritic initial $^{87}Sr/^{86}Sr$ ratio and further that significant differences exist in $^{87}Sr/^{86}Sr$ ratios from one mid-ocean ridge location to another (see refs 1, 2). The first reliable Pb-isotope compositions obtained from mid-ocean ridge basalts by Tatsumoto[3] showed that the evolution of their source had not involved a large fractionation in U/Pb ratio relative to the assumed whole Earth value. The available data base for Sr- and Pb-isotopes in mid-ocean ridge basalts has recently increased substantially[4–10], but only rarely

have Pb- and Sr-isotopes been measured on the same samples. In the past few years Nd-isotope compositions have been obtained on mid-ocean ridge and oceanic island basalts[11–14] and in those instances where Sr-isotope compositions have been reported for the same samples there is a clear negative correlation between $^{143}Nd/^{144}Nd$ and $^{87}Sr/^{86}Sr$ ratios. This correlation attests to a strong coherence in the fractionation of Rb/Sr and Sm/Nd during the evolution of the basalt sources. A similar comparison of the behaviour of U/Pb with Rb/Sr and Sm/Nd in oceanic basalt sources is more difficult, but the compilation of Pb- and Sr-isotope data made by Sun and Hanson[15] suggests that overall no such simple coherence exists. Further evaluation of these relationships has been hampered by the fact that Pb-, Nd- and Sr-isotope compositions have not been obtained on the same samples. An additional complication is that both Rb/Sr and $^{87}Sr/^{86}Sr$ ratios of ocean floor basalts may be modified by alteration processes operating on the sea floor. However, it has been shown that the glassy rims of pillow basalts generally provide the most reliable estimates of Rb/Sr and $^{87}Sr/^{86}Sr$ (ref. 2) and that the U-abundances of submarine basalts may be modified by interaction with seawater[16,17]. The reliability of many of the published Rb–Sr and U–Pb data on submarine crystalline basalts are thus very difficult to evaluate. The present study aimed to improve the existing situation by measuring $^{208}Pb/^{204}Pb$, $^{207}Pb/^{204}Pb$, $^{206}Pb/^{204}Pb$, $^{143}Nd/^{144}Nd$ and $^{87}Sr/^{86}Sr$ ratios together with the abundances of U, Pb, Sm, Nd, Rb and Sr all on the same samples of mid-ocean ridge basalt glasses from the Atlantic, Indian and Pacific oceans.

Analytical techniques

To minimise the possibility of contamination, glass rather than crystalline material was carefully handpicked from drilled or dredged basalt samples. Typically an aliquot of glass between 50 and 150 mg was dissolved and Pb separated electrochemically using a miniaturised version of the technique described by Arden and Gale[18]. Sr and Nd were subsequently isolated from the samples using cation and anion exchange techniques respectively[12]. U, Pb, Sm, Nd, Rb and Sr abundances were determined on a second aliquot of glass by mass spectrometric isotope dilution analysis. The purification techniques used were the same as the above with the addition of a reverse phase

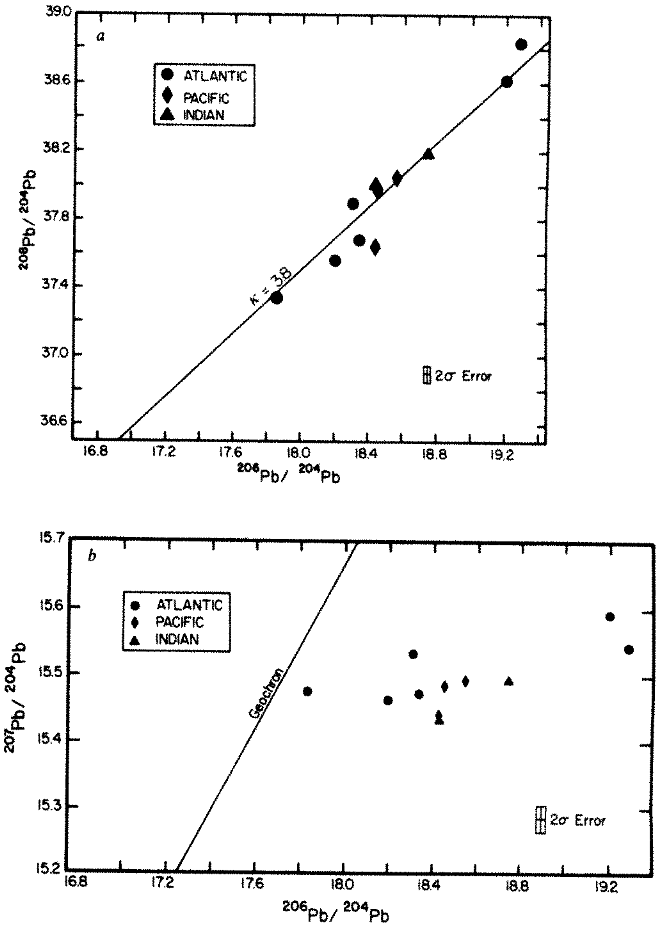

Fig. 1 *a*, Plot of $^{208}Pb/^{204}Pb$ versus $^{206}Pb/^{204}Pb$ for basaltic glass samples from the Atlantic, Indian and Pacific oceans. The line drawn is for a value of κ ($^{232}Th/^{238}U$) = 3.8. The errors indicated are average errors (Table 1). *b*, Plot of $^{207}Pb/^{204}Pb$ versus $^{206}Pb/^{204}Pb$ for basaltic glass samples from the Atlantic, Indian and Pacific oceans. The geochron has been constructed for 4.55 Gyr assuming initial Pb isotope compositions of Canyon Diablo[42]. The errors indicated are average errors for the analyses (see Table 1).

chromatographic procedure for the separation of U (ref. 19). The mass spectrometric techniques for the isotopic analysis of Pb, Rb, Sr, Sm and Nd have been described previously[12,20] and U was isotopically analysed using a triple-filament technique and ion-counting with a Daly detector. Procedural blanks are as follows: $U = 0.01$ ng; $Pb = 0.5$ ng; $Sm < 0.05$ ng; $Nd < 0.05$ ng; $Rb = 0.05$ ng; $Sr = 0.1$ ng.

Major element analyses of the glasses were obtained using an electron probe with energy dispersive analysis at the Department of Mineralogy and Petrology, Cambridge.

Results

The $^{208}Pb/^{204}Pb$, $^{207}Pb/^{204}Pb$, $^{206}Pb/^{204}Pb$, $^{143}Nd/^{144}Nd$ and $^{87}Sr/^{86}Sr$ ratios together with U, Pb, Sm, Nd, Rb and Sr concentrations for 11 mid-ocean ridge basalt glass samples are given in Table 1 and their major element compositions are listed in Table 2. The sample numbering system in Tables 1 and 2 is similar to that used by Melson *et al.*[21] where the letter prefix (A, I or P) denotes the ocean concerned and the following sequence of numbers and letter denote the latitude. Although the data in Table 1 are not fully representative of the Earth's mid-ocean ridge basalts they are adequate to demonstrate the nature of the isotopic variations that exist.

The Pb-isotope compositions for all of the samples are compared on plots of $^{208}Pb/^{204}Pb$ and $^{207}Pb/^{204}Pb$ versus $^{206}Pb/^{204}Pb$ in Fig. 1*a*,*b*. The $^{207}Pb/^{204}Pb$ and $^{206}Pb/^{204}Pb$ ratios of the samples all plot to the right of the geochron (4.55 Gyr isochron) and exhibit a positive correlation similar to that noted previously for mid-ocean ridge basalts[7,22]. The range of Pb-isotope compositions in the Atlantic samples is greater than that for either the Indian or Pacific oceans, but this may only reflect the limited size of the sample set.

$^{143}Nd/^{144}Nd$ and $^{87}Sr/^{86}Sr$ ratios are compared with the trend previously defined by mid-ocean ridge and ocean island basalts in Fig. 2. The samples exhibit a considerable range in both $^{87}Sr/^{86}Sr$ and $^{143}Nd/^{144}Nd$ ratios, and conform closely to the previously documented trend for oceanic volcanics. The highest $^{87}Sr/^{86}Sr$ ratios are found in basalt glasses from 37 °N and 45 °N on the Mid-Atlantic Ridge (A37.18N and A45.15N) close to the Azores platform (refs 10, 23). Conversely the sample with the lowest $^{87}Sr/^{86}Sr$ and highest $^{143}Nd/^{144}Nd$ ratio is from the Mid-Atlantic Ridge at 6 °S (A05.47S).

The most important new observation to be made about these data is probably the association of the least radiogenic Pb isotope and Sr isotope compositions and vice versa (Fig. 3). Overall there is a good positive correlation between the $^{87}Sr/^{86}Sr$ and $^{206}Pb/^{204}Pb$ which indicates a strong coherence between U/Pb and Rb/Sr during the evolution of the mid-ocean ridge basalt source region. Note that the Pb- and Sr-isotope data reported for Icelandic and Reykjanes Ridge basalts[8,24] are consistent with the correlation shown in Fig. 3, but in general, data reported from other oceanic islands do not show such a consistent correlation (see compilation in ref. 15).

The abundances of U, Pb, Rb, Sr, Sm and Nd in the basalt glasses show considerable variation (Table 1), for example, Rb/Sr ratios vary by more than an order of magnitude from 0.003 to 0.044 and U/Pb ratios range from 0.077 to 0.587. With the exception of sample A37.18N the Rb/Sr and U/Pb ratios are positively correlated (Fig. 4). A second and apparently pure 5-mg aliquot of A37.18N has been analysed and found to have $Rb/Sr = 0.065$, a factor of two higher than the first sample. The reason for the highly variable Rb abundance in this glass is not understood. Correlations between $^{87}Rb/^{86}Sr$ and $^{87}Sr/^{86}Sr$ and $^{238}U/^{204}Pb$ and $^{206}Pb/^{204}Pb$ ratios respectively are poor as seen in a plot of $^{238}U/^{204}Pb$ versus $^{206}Pb/^{204}Pb$ in Fig. 5 and do not provide any evidence for discrete mantle fractionation events.

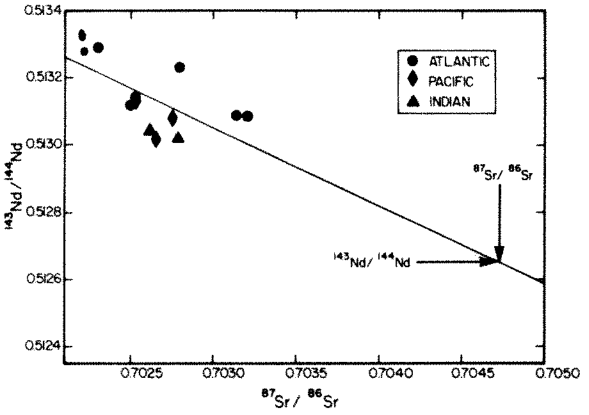

Fig. 2 Comparison of $^{143}Nd/^{144}Nd$ and $^{87}Sr/^{86}Sr$ ratios of basalt glasses from the Atlantic, Indian and Pacific oceans with the trend defined previously for oceanic volcanics[11-13]. The arrows indicate the estimated $^{143}Nd/^{144}Nd$ and $^{87}Sr/^{86}Sr$ ratios of the bulk Earth[12,13].

The major element analyses of the samples (Table 2) are typical of those for mid-ocean ridge tholeiites (see, for example, ref. 25) with SiO_2 contents ranging from 49.12 to 52.47 wt %. None of the major element abundances or ratios such as $MgO/(MgO+FeO)$ show any clear correlation with trace element abundances, or abundance ratios such as Rb/Sr or U/Pb.

Discussion

The $^{143}Nd/^{144}Nd$ and $^{87}Sr/^{86}Sr$ ratios of the glasses are respectively greater than and less than the model bulk Earth values for these ratios and are consistent with the negative correlation identified previously for oceanic basalts[10-12]. It has been suggested that a unidirectional transport model involving the extraction of silicate melt from the mantle to leave a residuum with lower Rb/Sr and higher Sm/Nd ratio than the original would produce with time the Nd- and Sr-isotope characteristics of mid-ocean ridge basalts[12,26-28]. The general correlation between $^{206}Pb/^{204}Pb$ and $^{87}Sr/^{86}Sr$ ratios in mid-ocean ridge basalts suggests that there was a coherence between U/Pb and Rb/Sr during the evolution of the basalt source region. Is this correlation consistent with the simple unidirectional transport models that have been used to accommodate the Nd and Sr data? An assessment of this possibility is made difficult by uncertainties in the values of U and Pb distribution coefficients

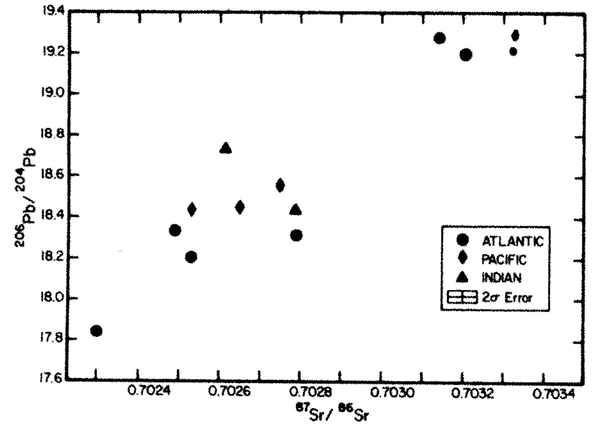

Fig. 3 Plot of $^{206}Pb/^{204}Pb$ versus $^{87}Sr/^{86}Sr$ for basaltic glasses from Atlantic, Indian and Pacific oceans. Average error is indicated.

in silicate systems, by the role of minor U- and Pb-bearing phases in the source region, and the uncertainty of the bulk Earth lead isotope composition. Whereas some ocean island basalts have $^{206}Pb/^{204}Pb$ ratios higher than any reasonable estimate of the bulk Earth Pb-isotope composition[29,30], the relationship of the Pb-isotope compositions of mid-ocean ridge basalts to the bulk Earth is less certain. If the bulk Earth Pb-isotope composition lies on the geochron (plotted for an assumed of 4.55 Gyr) in Fig. 1*b*, as is generally assumed, then all of the ocean ridge basalts under discussion here have $^{206}Pb/^{204}Pb$ ratios higher than the bulk Earth value. If the previous interpretations of the Nd and Sr-isotope correlation in oceanic basalts are applied to the above Pb- and Sr-isotope data, then those samples with highest $^{87}Sr/^{86}Sr$ ratios are considered to have been derived from less depleted (in a time-integrated sense) mantle than samples with lower $^{87}Sr/^{86}Sr$. Extrapolation of the $^{206}Pb/^{204}Pb$ versus $^{87}Sr/^{86}Sr$ correlation to a model $^{87}Sr/^{86}Sr$ ratio of the bulk Earth (~ 0.7050) would suggest that the $^{206}Pb/^{204}Pb$ ratio of the bulk Earth is ~ 21.3, a much greater value than other estimates of the bulk Earth Pb-isotope compositions. Furthermore if a unidirectional transport process effected a decrease in Rb/Sr and a concomitant increase in U/Pb in the residual mantle, then the lowest $^{87}Sr/^{86}Sr$ ratios would be associated with the highest $^{206}Pb/^{204}Pb$ ratios—the opposite to what is observed! Clearly a more complex model of Earth evolution than a simple unidirectional transport model, is required to accomodate the Pb-, Nd- and Sr-isotope data.

At this stage several more complex models should be considered. For example, it has been suggested[31,32], that Pb may have been partitioned into sulphide phases preferentially to U and subsequently located in the core during Earth differentiation. If, for example, such a process increased the U/Pb ratio in some part of the mantle, but not the Rb/Sr ratio, then at present it would have a $^{87}Sr/^{86}Sr$ ratio of 0.705 (the bulk Earth value) and a $^{206}Pb/^{204}Pb$ ratio in excess of the bulk Earth value. To produce the correlation in Fig. 3 this source or magmas derived from it would have to mix with those from another mantle source that had suffered a reduction in Rb/Sr ratio but comparatively little change in U/Pb ratio. Alternatively other workers have used models involving bidirectional transport of material between the mantle and the continental crust[33,34] to generate the Pb- and Sr-isotope compositions of oceanic volcanics. Recently Doe and Zartman[35], O'Nions *et al.*[36] and Evensen *et al.*[37] have pointed out that the continental crust may be considered as two reservoirs as far as Pb-isotopes are concerned. Because U is preferentially concentrated in the upper parts of the continental crust, the upper crust evolves with a relatively more radiogenic Pb-isotope composition than the lower part. Any preferential recycling of upper crust into the mantle would result in a mean Pb-isotope composition of the mantle more radiogenic than the bulk Earth and could account for the observed range of Pb-isotope composition found in oceanic basalts. Whether or not all the features of Pb-, Nd- and Sr-isotope chemistry of mid-ocean ridge basalt glasses can be reproduced by such models of continent recycling must await the results of further computations. Nevertheless, adopting such models would implicitly favour a continuous rather than episodic evolution of Pb-isotopes in the mantle.

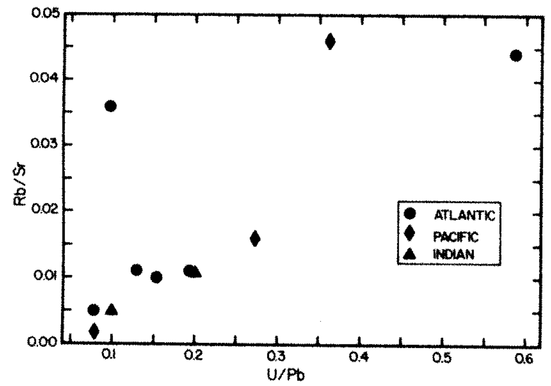

Fig. 4 Plot of U/Pb and Rb/Sr in basaltic glasses from the Atlantic, Indian and Pacific oceans.

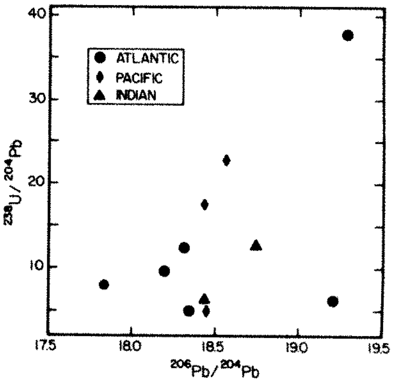

Fig. 5 Plot of $^{238}U/^{204}Pb$ versus $^{206}Pb/^{204}Pb$ for basaltic glasses from the Atlantic, Indian and Pacific oceans.

The comparatively small variations in Pb-, Nd- and Sr-isotope compositions in the glasses require that the time-integrated (over the duration of Earth history) Rb/Sr, U/Pb and Sm/Nd ratios in the various source regions must have been quite uniform. This is in marked contrast to the order of magnitude variation of Rb/Sr and U/Pb in the glasses. Such large variations could not be generated from a uniform source composition if the partial melting which produced the basalts followed a simple equilibrium melting model (for example see ref. 38) and the primary magmas produced underwent only small amounts of subsequent crystallisation differentiation. Thus it must be inferred either that the processes of basalt magma generation and evolution of mid-ocean ridges can effect much greater fractionation of Rb/Sr, U/Pb and Sm/Nd than is often appreciated or alternatively some mantle process effects large, but transient fractionation before the melting event. The petrogenetic utility of trace element abundances in oceanic basalts is severely limited until some resolution of these alternatives can be made.

We thank F. Aumento, E. Bonatti, S. R., Hart and W. Melson and the Deep Sea Drilling Program for samples, Genevieve Wesselmann for technical assistance, and Dr J. V. P. Long for electron microprobe facilities. This work was supported by grants from the NSF (EAR-75-20891) and NASA (NSG-7466).

Tholeiitic basalt–rhyolite magmatism and massive sulphide deposits at Matagami, Quebec

P. J. MacGeehan[*] & W. H. MacLean

Abitibi Project, Department of Geological Sciences, McGill University, 3450 University Street, Montreal, Quebec, Canada H3A 2A7

Noranda-type massive sulphide deposits in some Archean greenstone belts of the Canadian Shield occur in tholeiitic volcanic sequences. The tholeiitic rocks belong to basalt–rhyolite bimodal suites with low Al_2O_3, high Na/K ratios, high iron contents, and well-defined iron enrichment trends.

IN Archean greenstone belts of the Canadian Shield Fe–Zn–Cu massive sulphide deposits of the Noranda-type are invariably described as occurring in calc-alkaline volcanic rocks[1–4]. Within each belt the volcanic succession typically consists of a laterally extensive sequence of tholeiitic basalt forming the lower two-thirds of the stratigraphy (Fig. 1*a*), overlain by volcanic rocks of calc-alkaline attribution (basalt, andesite, dacite and rhyolite) that form thick accumulations at discrete volcanic centres[1,5–7]. The accompanying massive sulphide deposits, ranging up to 2×10^8 tonnes in size (~5% Zn, 2% Cu), are composed mainly of pyrite, pyrrhotite, sphalerite and chalcopyrite, and occur as stratiform lenses clustered within the 'calc-alkaline' centres, most commonly on the flanks of rhyolite domes or other felsic accumulations. The sulphides were deposited as chemical sediments on the ancient seafloor[8], around or downslope from exhalation centres (now mineralised alteration pipes) that emitted hot metalliferous brines akin to those now found at the bottom of the Red Sea[9]. The massive sulphides thus form part of the original stratigraphy, and their apparent association with calc-alkaline rocks has historically made the latter an essential criterion for defining mineral exploration targets. However, in one of these large Archean volcanic centres, at Matagami, Quebec, this relationship does not hold; the massive sulphide deposits, while originally thought to lie within calc-alkaline rocks[10], are now shown to occur within a bimodal basalt-rhyolite suite of tholeiitic affinity[11,12]. Their apparent 'calc-alkaline' affinity is due to the widespread hydrothermal alteration that accompanied sub-seafloor geothermal activity, as will be discussed elsewhere. In this article we present evidence of the tholeiitic nature of these rocks, discuss their relationship to the ore deposits, and suggest that other Noranda-type massive sulphide deposits may occur in tholeiitic volcanic centres.

Geology of the Matagami district

The pertinent stratigraphy at Matagami consists of 80% basalt and 20% rhyolite (Fig. 1*b*,*c*). It contains over 18 mostly Zn-rich stratiform massive sulphide lenses, all closely associated with rhyolites. These rocks and ores have been intruded by the Bell River Igneous Complex and many of its subsidiary dykes and sills, then metamorphosed to the greenschist facies, and folded into a westward plunging anticline[13] (Fig. 2). The sulphide

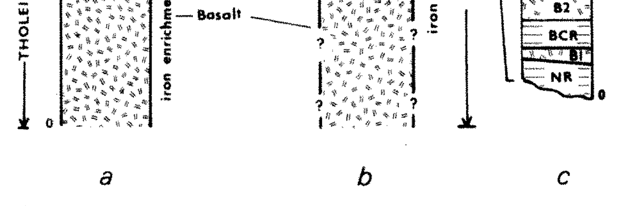

Fig. 1 Comparison of the stratigraphy in a typical Archean greenstone belt: *a*, to that at Matagami; *b*, with detail for Matagami in *c*. B1–B7 are basalts; NR, Norita rhyolite; BCR, Bell Channel rhyolite; GLR, Garon Lake rhyolite; FP, feldspar porphyry (andesite).

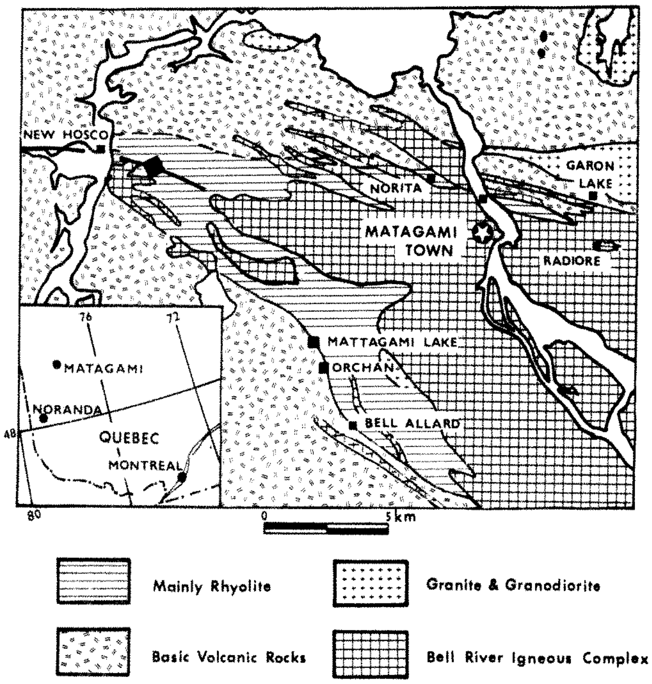

Fig. 2 Simplified geology of the Matagami district (after Sharpe[13]).

deposits, ranging up to 25 Mtonnes in size, occur within a 1 km thick stratigraphic section, and they now form two linear mineralised belts, one on either side of the anticline. On the south limb the deposits (Bell Allard, Orchan, Mattagami Lake, New Hosco) are all located at the base of the 'Key Tuffite'[14,15], a cherty tuffaceous unit that lies on top of a massive rhyolite, whereas those on the north limb are associated with rhyolites at several stratigraphic horizons: Norita rhyolite (Norita mine, Bell Channel No. 1), Bell Channel rhyolite (Bell Channel No. 4, Radiore), and Garon Lake rhyolite (Garon Lake mine)[11,12].

Stratigraphy

The volcanic rocks on the north limb of the anticline have been mapped and sampled in detail, and each unit has been analysed for major and several trace elements (Fig. 4). The stratigraphic sequence is composed of seven pillowed basalt units, a pillowed andesite and three rhyolite flows (Fig. 1*c*). The basalts are mostly aphyric or weakly plagioclase–phyric, but one unit, B2, is coarse grained throughout and contains abundant phenocrysts of plagioclase and pyroxene (now uralitised) in about equal proportions. The three rhyolite units are spherulitic flows which form domal accumulations up to 150 m thick, with associated pyroclastic material. All three units contain phenocrysts of quartz (inverted β-quartz) and sodic plagioclase, and rare granophyre xenoliths (Fig. 3*a*). The Bell Channel rhyolite also contains microphenocrysts of tridymite (inverted) (Fig. 3*b*)[12].

These volcanic rocks are intruded by concordant gabbro sills ranging from 50 to 250 m thick which grade laterally into underlying feeder dykes connected to the Bell River Igneous Complex. Contact features bordering these minor intrusions indicate they were emplaced contemporaneously with the extrusive rocks, and some indeed may represent lateral feeders to overlying flows[11].

Petrology and primary geochemical trends

All the volcanic rocks in the district have undergone a weak pervasive hydration, but alteration was more intense in the vicinity of the sulphide deposits; there, the rhyolites are chloritised and the underlying basalts are strongly spilitised and silicified. However, the stratigraphic sequence was extensively sampled for more than 5 km along strike, and the primary geochemical features of each rock unit were established (Fig. 4) using samples in which the primary mineral fabric was well preserved.

Basalt: the seven basalt units consist of plagioclase (saussuritised), pyroxene (uralitised), and minor opaque oxide set in devitrified glass that is either chloritic (B2–B4) or quartzofeldspathic (B5–B7). They are all quartz normative and have low Al_2O_3, high Na/K ratios, and high iron contents. Plots of the oxides against differentiation index[16] (Fig. 4) show minor fractionation of the units, but they all cluster at the basaltic end of the diagram, well separated from plots of the rhyolites. On an AFM diagram (Fig. 5*a*) the basalts (B2–B5) follow a progressive iron enrichment trend within the tholeiitic field, and this is re-emphasised on an MgO versus FeO* diagram (Fig. 5*b*; plots of Fe/(Fe+Mg) versus Si (refs 17, 18), FeO* or SiO_2 versus FeO*/MgO (ref. 19) similarly emphasise this relationship). Rocks of unit B5, which show maximum iron enrichment, first crystallised plagioclase and pyroxene, followed by magnetite, sodic feldspar, quartz and albite—the latter two minerals forming a spherulitic mesostasis to the other grains (Fig. 3*c*). This paragenesis provides strong petrographic support for a tholeiitic trend, and shows the transition from iron enrichment to alkali enrichment during the crystallisation of individual pillows.

Rhyolite: the three rhyolite units have high SiO_2 contents, but low Al_2O_3, high Na/K ratios, and high iron contents, like the basalts (Fig. 4). They plot at the alkali end of the tholeiitic field on an AFM diagram (Fig. 5*a*), but have normative plagioclase compositions around $An_{20}(An_{18.5-23})$ and are thus 'dacites' according to most rock classifications[20,21]. There is corroborating petrographic evidence that the plagioclase phenocrysts originally had this composition. All three units contain quartz and plagioclase phenocrysts and micrographic intergrowths (Fig. 3*a*), indicating they were crystallising on a cotectic in the Q–Or–Ab–An system before extrusion. However, in at least one unit (BCR), β-quartz was succeeded by tridymite after extrusion (Fig. 3*b*), yielding a minimum magma temperature of 867 °C (ref. 22) but probably as high as 935 °C (ref. 12). These temperatures are well above the liquids of melts crystallising albite, but close to that of melts crystallising plagioclase An_{20} in

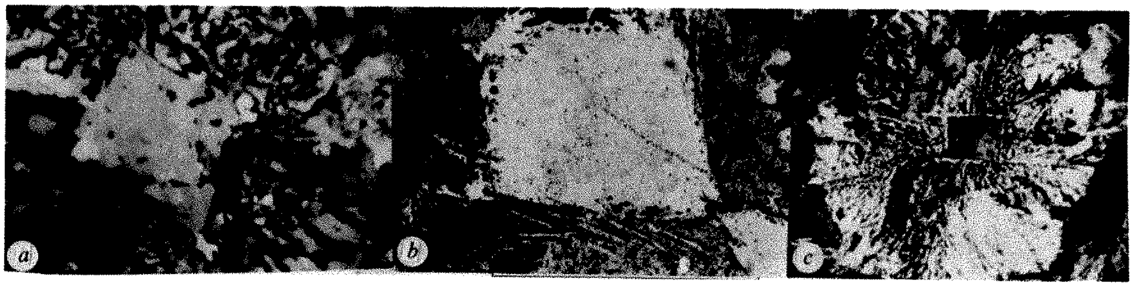

Fig. 3 *a*, From a granophyre fragment in the Garon Lake rhyolite; central crystal is inverted β-quartz surrounded by a micrographic intergrowth of quartz (white) and albite (grey-black). *b*, Tridymite phenocryst with reticulate borders, flanked by elongate tridymite microlites, now inverted to quartz (from the Bell Channel rhyolite). *c*, Spherulitic quartz–albite intergrowth mantling plagioclase and magnetite grains in the mesostasis of B5 basalt.

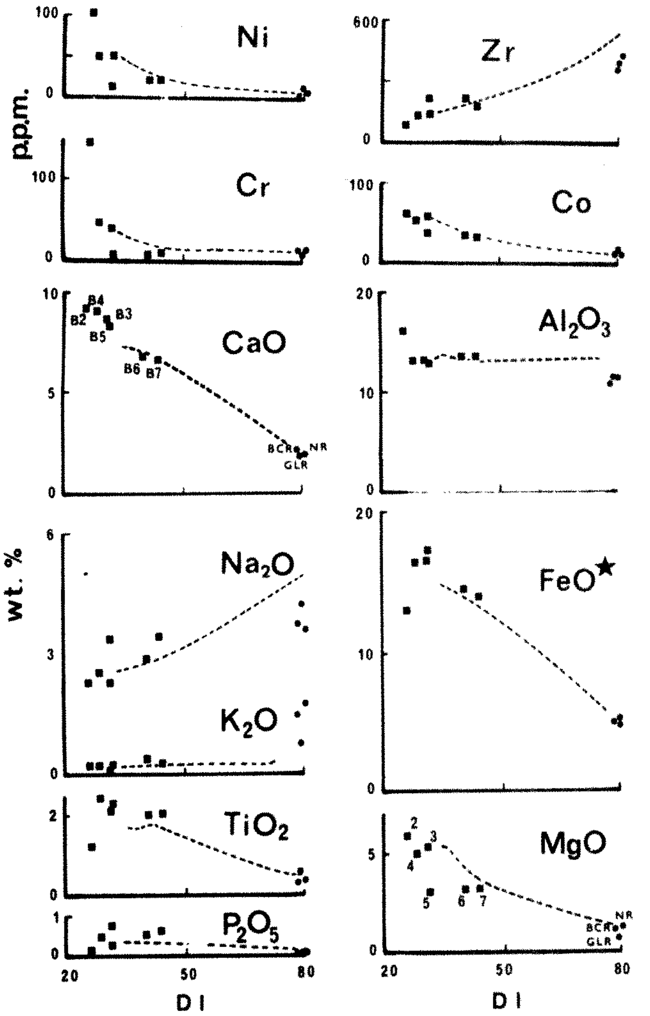

Fig. 4 Major oxides and trace elements[11,12] plotted against differentiation index (DI) show the bimodal distribution of the volcanic suite. ■, basalts; ●, rhyolites. The dashed line is the liquid-line-of-descent for the gabbro–granophyre sill[12] that was intruded contemporaneously with volcanism.

the quinary system Q–Or–Ab–An–H_2O at 2 kbar pressure[23,24]. As noted above, silicic rocks with these high normative An contents are generally classed as dacite, but our three units have SiO_2 contents >10% higher than equivalent dacites in Nockolds' classification[25]. Thus, although these rocks are actually dacites, we will follow the usage of other workers in the Canadian Shield for the time being who call these rocks rhyolite based on their high SiO_2 content[4,27,28] and the present albitic composition of the plagioclase phenocrysts.

Contemporaneous gabbro sills

The contemporaneous gabbro sills have compositions very similar to the basalts[12,13], and each sill fractionated along an iron enrichment trend. One highly fractionated gabbro-granophyre sill was studied in detail[12], and its chemical composition and fractionation trend (Figs 4, 5) place it well within the field of tholeiitic rocks, where it has an iron enrichment trend comparable with that of the well established tholeiitic suite from the Thingmuli Central Volcanic Complex in Iceland[18] (Fig. 5*b*). The trend in the liquid line-of-descent of this sill (dashed lines, Figs 4, 5) is believed to provide a good approximation of the probable fractionation path of the volcanic rocks at Matagami[12].

Interpretation

Using differentiation index as a monitor of progressive fractionation (Fig. 4) the aphyric basalts have chemical compositions essentially identical to successive liquids in the gabbro-granophyre sill (Fig. 4), and follow a comparable but more extreme iron enrichment trend (Fig. 5). Furthermore, each successive flow is more fractionated, indicating that the whole suite was derived from a common parent by progressive fractionation. This is supported by the trace element distributions in the basalts. Cr, Ni and Co have high concentrations in the earliest basalt flows, and decrease rapidly with fractionation, whereas Zr has a low initial value but becomes progressively enriched in the later flows. This is identical to their distribution in the gabbro–granophyre sill (dashed line, Fig. 4), and similar to that of Skaergaard[28], Thingmuli[29], and other tholeiitic suites. Preliminary studies on the REE content of the basalts and the sill indicate both have similar distribution patterns (Fig. 6*a*). These are typical of tholeiites in their low REE content and lack of LREE enrichment, and similar to those of modern oceanic basalts[30] and to that of the Skaergaard liquid after crystallisation of the Middle Zone[31]. Although highly fractionated, they also plot in the field of 'ocean floor' and 'within-plate' tholeiites on a Ti–Zr–Y diagram[32] (Fig. 6*b*).

The rhyolites and the granophyre of indicated tholeiitic affinity, have similar mineralogy and texture and almost identical composition (Fig. 4). However, both have significantly higher FeO*, MgO (and CaO), and higher temperature of crystallisation than the Thingmuli rhyolites (Fig. 5*b*), consistent with their calcic compositions. The granophyre represents a

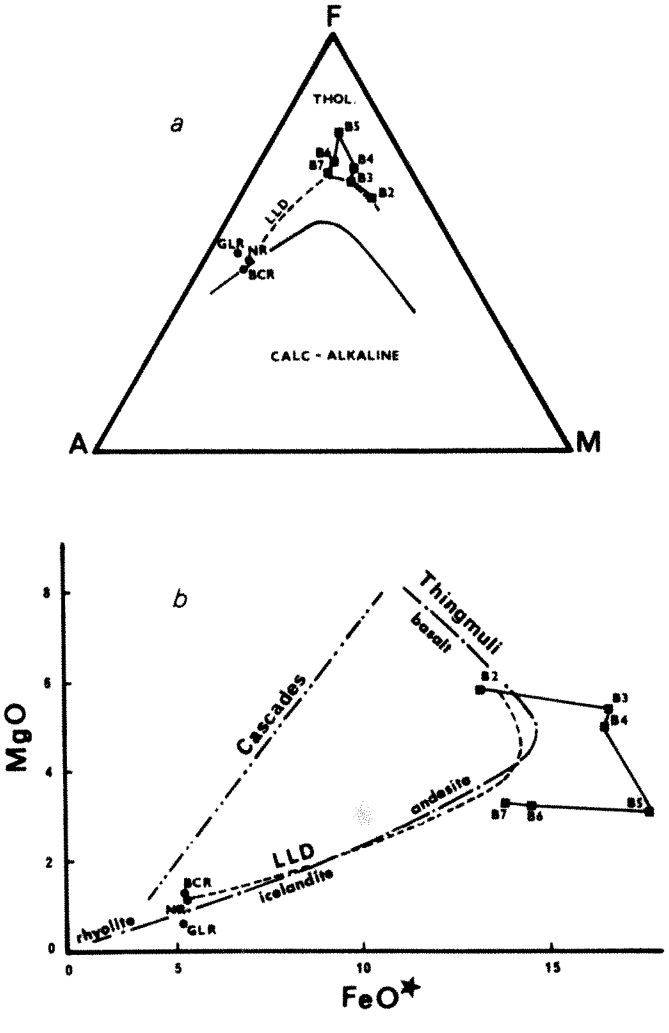

Fig. 5 *a*, AFM plot (wt%) of the volcanic units and the liquid-line-of-descent (LLD) of the gabbro–granophyre sill (dashed). The dividing line (solid line) for the tholeiitic and calc-alkaline fields is from Irvine and Baragar[20]. *b*, MgO versus FeO* (total iron) plot with comparison to Thingmuli (tholeiitic) and Cascades (calc-alkaline).

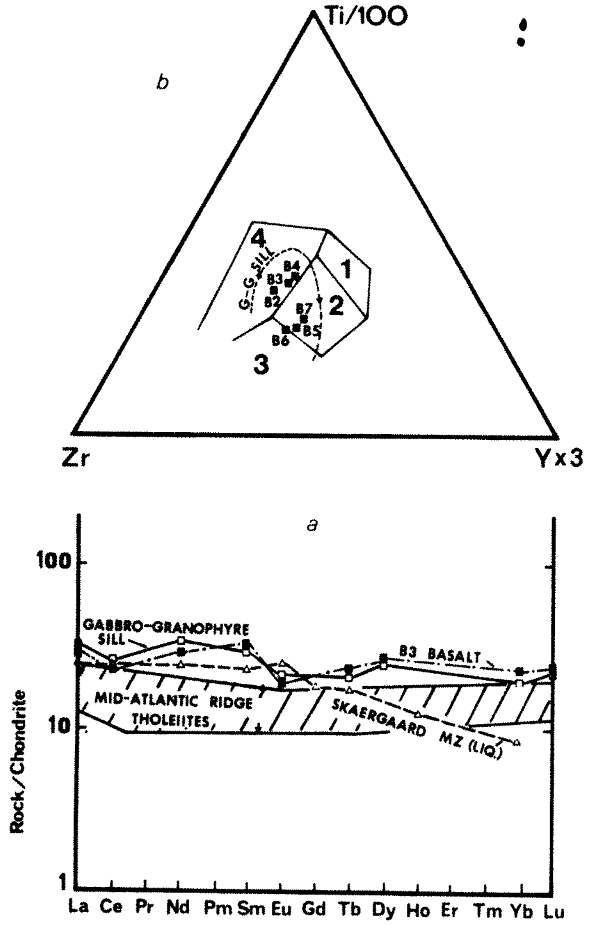

Fig. 6 *a*, Rare earth element analyses for B3 basalt and the gabbro–granophyre sill, compared to the middle zone (MZ) liquid of the Skaergaard intrusion[31] and the Mid-Atlantic Ridge tholeiites from the FAMOUS expedition[30]. *b*, Ti–Zr–Y plot[32] of basalts and sill. Fields **1** and **2** are low-K basalts; **2** is ocean floor tholeiite; **3** is calc-alkaline basalt; and **4** is within-plate basalt. Analyses for REE were by neutron activation at X-ray Assay Laboratories, Toronto, Canada, and chondrite-normalised using the values for the Leedey chondrite[46].

residual melt derived by fractionation of a parental magma very similar in composition to the basalts (dashed line, Fig. 4), leaving but little doubt that it and the rhyolites shared a common origin—as residual melts derived through progressive fractionation of a parental tholeiitic basaltic magma.

Preliminary studies on the underlying Bell River Igneous Complex indicate that its rocks too are very iron-rich[33], and the layered gabbro–anorthosite series is not disrupted by gabbro dykes and sills that transect the overlying rocks. We interpret these field and chemical relations to indicate a comagmatic source, with the Complex emplaced high into the volcanic pile (probably within 1 km of the surface), and itself acting as a holding chamber while supplying differentiated magma to overlying flows and sills.

Matagami lies at the western end of a linear belt of mixed tholeiitic volcanic rocks and layered gabbroic and anorthositic plutons which includes the Chibougamau mining district 250 km to the east[34]. In geologically younger parts of the Earth's crust, thick tholeiitic volcanic sequences with associated large basic layered intrusions are found only in areas of tensional tectonics[35], for example, Skaergaard, Duluth, and Scottish Tertiary complexes. The similarity of the younger examples to these older rocks suggests the Matagami–Chibougamau volcanic belt also formed in a tensional environment.

Implications

The ores at Matagami are typical Archean Noranda-type deposits being (1) polymetallic (Fe–Zn–Cu–Ag–Au) massive sulphides of volcanogenic exhalative origin, (2) stratiform in configuration, and (3) associated with rhyolites near the tops of thick sequences of essentially basic submarine volcanic rocks[36]. In form and origin they are identical to younger volcanogenic types, but in metal content or in type of associated volcanic rock they may differ[37,38]. The younger deposits are widely regarded as falling into two major classes: (1) Fe–Cu-rich ores in basalts of tholeiitic affinity in tensional tectonic settings (Cyprus-type: spreading ridge; Besshi-type: back arc), and (2) Fe–Zn–Cu–Pb ores in rhyolite and dacite of calc-alkaline affinity developed along consuming plate margins (Kuroko-type)[36,39,40]. Although Noranda-type deposits contain only minor or trace amounts of Pb, they have been compared most frequently with the Kuroko-type because of their association with rhyolites and the apparent calc-alkaline nature of the volcanic sequences. Consequently, geological thought and exploration strategy in shield areas have been unduly preoccupied with the 'calc-alkaline' association of these ores, and by analogy, with compressional zones in the Earth's crust.

However, genesis of these massive sulphide ores is intimately related to sub-sea floor geothermal activity[11,41–43] during which Fe, Mg, Cu, Zn and many other elements are leached from large volumes of the underlying volcanic rocks and deposited at the sediment–seawater interface. It is these hydrothermally altered volcanic rocks, whose $^{87}Sr/^{86}Sr$, $^{18}O/^{16}O$ and $^{34}S/^{32}S$ ratios[42,43] and major and trace element geochemistry[11,12] have been so strongly disturbed, that are often described as 'calc-alkaline'. The apparent 'calc-alkaline' affinity of hydrothermally altered tholeiitic volcanic rocks in many mining districts may thus be the inevitable consequence of sub-seafloor geothermal activity, as will be outlined elsewhere.

Thus, Noranda-type massive sulphide deposits do occur in association with tholeiitic volcanic rocks, both here in Matagami, in the Flin Flon–Snow Lake mining district[44], and apparently in several other districts[45]. This and other evidence also indicates they formed in tensional environments in the Earth's crust. Therefore, we conclude that sequences of submarine volcanic rocks containing rhyolites, whether of tholeiitic or calc-alkaline affinity, are prime exploration targets for Noranda-type massive sulphide ores.

We thank R. F. Martin, A. J. Hynes, D. Francis and C. Jay Hodgson for critically reviewing the manuscript. Funding was provided by FCAC grant 649 and NSERC grant A7719.

Genetic variance of laboratory outbred Swiss mice

M. Catherine Rice & Stephen J. O'Brien*

Laboratory of Viral Carcinogenesis, National Cancer Institute, National Institutes of Health, Bethesda, Maryland 20205

The extent of allelic variation has been estimated at 46 structural gene loci within three major colonies of Swiss mice and between inbred derivative strains. The colonies have retained nearly the same amount and type of variation found in natural murine or human populations despite laboratory propagation for more than 50 years (175 generations). The population genetic structures of the Swiss mouse colonies were comparable to an island population in which random fixation, and not inbreeding or population bottlenecks, is apparently responsible for slight losses in genetic variance.

RODENTS provide a general standard in toxicological and carcinogenesis testing[1,2] and laboratory mice (*Mus musculus*) are especially useful because they are inexpensive, available in large number and have short lifespans. A major advantage is the availability of numerous inbred strains homozygous for over 98% of their genetic loci. In addition, considerable genetic information about the differences between strains has accumulated from research on mouse genetics, oncology and toxicology[3-5]. However, the divergence between inbred strains is now a source of criticism of their use for estimating human risk[1,2]. The problem stems from the expression of certain alleles which influence response to chemicals in various inbred strains, many of which were specifically selected to respond to particular chemicals or to have a high spontaneous incidence of tumours[3-6]. Thus, some toxicology testing protocols now involve laboratory outbred mice, on the rationale that such strains more closely resemble genetically heterogeneous human populations.

A key assumption in the use of outbred stocks is their genetic similarity to outbred mouse or human populations. Festing[7] has argued that the variation within an outbred stock is considerably smaller than that between inbred strains and has proposed the use of a panel of different inbred strains in a factorial design[7,8]. The true extent of gene variability in laboratory outbred stocks is unknown[8-10], and no data have been reported on stocks of the Swiss mouse, the most commonly used outbred mouse line.

We have applied the techniques and concepts of population genetics to the biochemical genetic characterisation of outbred Swiss mice from three major production colonies known to supply a large proportion of such mice for carcinogenesis and toxicological testing. The extent of gene–enzyme electrophoretic variation at 46 structural genes is presented in addition to the typing of several inbred Swiss strains. The results are analysed with respect to the following questions: (1) Do different isolated Swiss mouse colonies differ from each other in their population genetic structure? (2) Do outbred Swiss mice contain the same amount of variation observed in wild mouse populations, or has it been diminished by inbreeding, possibly through bottlenecks or by protection from the selective pressures of the wild state? (3) Is variation in Swiss mice qualitatively different (that is, with different variable loci, alleles or allele frequencies) from that in wild populations? In addition, the results of the analysis are related to considerations of population genetic theory of isolated populations.

History of the three Swiss mouse colonies

The original colony of Swiss mice in the US started from nine mice brought from Lausanne, Switzerland, in 1926 by Clara Lynch. Lynch[11] documented the genealogical history of the outbred strain starting from the Pasteur Institute in Paris until it reached the Rockefeller Institute where Webster maintained and dispersed Swiss and Swiss–Webster mice to researchers and commercial dealers. The three major colonies diverged from the Rockefeller colony in the late 1930s. The derivation of the outbred and inbred Swiss mouse strains is reconstructed in Fig. 1.

An estimate of gene–enzyme variation in Swiss mice

Between 40 and 50 6-week-old female non-sibling Swiss mice were obtained from each of the three colonies in addition to several mice from the Swiss inbred lines, from BALB/c and from C57BL/6. Extracts prepared from kidney, liver, red blood cells and plasma from each animal were subjected to gel electrophoresis and developed histochemically for 26 enzymes and haemoglobin. The 27 systems were selected from isozyme systems used in our laboratory for studies in somatic cell genetics[12-14]. The extent and character of allozyme (allelic isozyme) variation at each of 46 loci (Table 1) were determined by comparing the allozyme phenotype with the enzyme mobilities obtained from BALB/c or C57BL/6 mice standards run in the same gel[3,15-17]. The utility of these systems in somatic cell genetics does not depend on allozyme polymorphism, and thus minimises the bias of published systems which are mostly polymorphic[18]. Of the 46 loci, 38 have been mapped to specific chromosomal sites in the mouse (Table 1), indicating that they are genetically autonomous of each other.

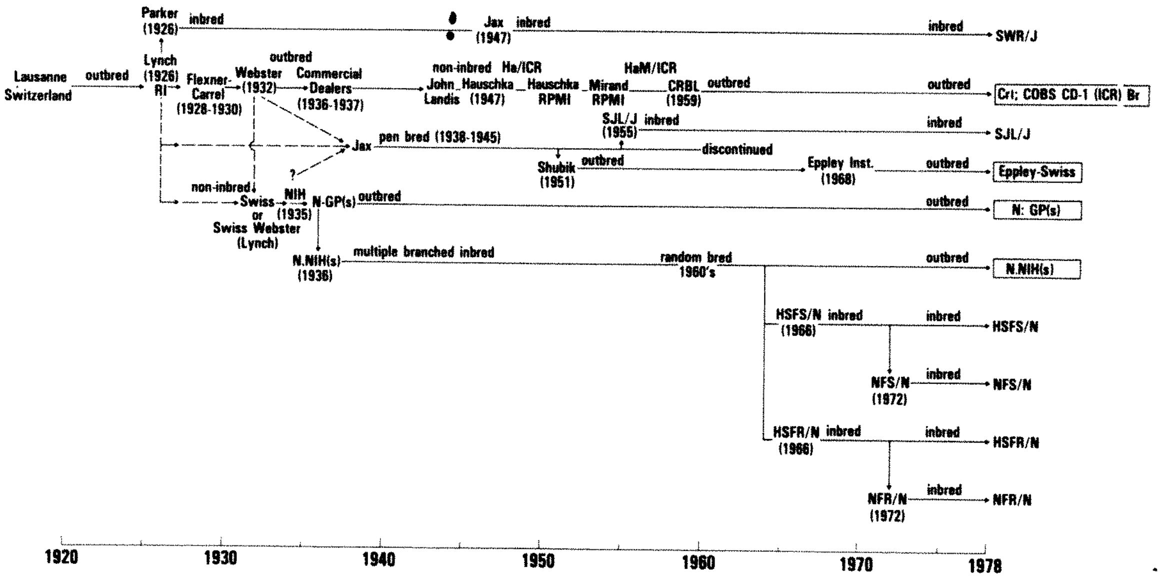

Fig. 1 Genealogical history of Swiss outbred mice and inbred derivatives. **CD1 colony:** In 1947, Hauschka established the Ha/ICR outbred stock from 100 female and 30 male 'Swiss–Webster' mice obtained from John Landis in Hagerstown, Maryland[47]. The origin of Landis' stock is obscure. When Hauschka moved from the Institute of Cancer Research, Philadelphia, to Roswell Park Memorial Institute, he passed some of the mice to E. A. Mirand. In 1957, Mirand sent 50 female mice to Charles River Breeding Laboratories where they founded the Cr1 : COBS.CD-1(ICR)BR colony (G. Pucak, personal communication). The CD-1 stock is now bred on a 1 × 1 system adopting the 'Poiley method', a systematic circular method used to maximise outbreeding. A protected nucleus colony of 300–400 breeders is kept in sterile plastic film isolators and several production colonies produce 10,000–12,000 CD-1 pups each per week. To maintain homogeneity, pups from different production colonies are added to the nucleus periodically. **Eppley–Swiss colony**: The Jackson Laboratory, Bar Harbor, received Swiss and Swiss–Webster outbred mice from three sources (C. Lynch, L. Webster and one unknown) between 1938 and 1945 (ref. 3) (J. Staats, J. Dorey, personal communications). These outbred lines were pen bred until 1955. In 1951, P. Shubik, Chicago Medical School, obtained Swiss mice from the pen-bred colony (B. Toth, personal communication) and started a closed, outbred colony. Shubik moved the colony to the Eppley Institute, Omaha, Nebraska, in 1968, where it is now bred on a 1 × 1 scheme, using an extensive labelling system to insure random breeding in an isolated breeder colony of 150–180 pairs. The Eppley–Swiss colony produces 18,000–26,000 mice per yr. **N.NIH(s) colony**: In 1935 the NIH received an undetermined number of outbred Swiss mice from the Rockefeller Institute that were the founders of the general purpose colony N : GP(s). In 1936, the N.NIH(s) was derived from the N : GP(s) colony. The N.NIH(s) colony was bred from 1936 to the 1960s by a multiple-branched inbreeding system described as a "brother–sister mating without following any systematic plan" (ref. 40). In the early 1960s a strict random mating scheme was resumed for the N.NIH(s) stock (C. T. Hansen, personal communication). The N.NIH(s) stock was rederived in 1972 by hysterectomy and foster nursing of mice to establish a specific pathogen-free (SPF) colony[48]. This nucleus colony consists of 120 pairs, is bred by a circular pair mating system and is selected for high productivity (C. T. Hansen, personal communication). The N.NIH(s) colony produces 140,000 mice per yr and the N : GP(s) colony 110,000 per yr. **Inbred strains**: In 1926, an inbred derivative of Lynch's Swiss strain, SWR, was established by Raymond Parker at the University of Toronto. In 1947, the SWR line was supplied to the Jackson Laboratory which continued the inbred line as SWR/J. The SJL/J strain was derived from the pen-bred Swiss strain at the Jackson Laboratory around 1955 when the outbred line was discontinued. In 1966, two inbred lines were derived from the N.NIH(s) colony. These lines were selected for their reaction to histamine after treatment with *Bordetella pertussis* and were thereby named HSFR/N (histamine-sensitive-factor resistant) and HSFS/N (histamine-sensitive-factor sensitive). In 1972, two new inbred lines, NFS/N and NFR/N, were rederived from HSFS/N and HSFR/N, respectively. During derivations of the present colonies, there were various periods of bottlenecks of unconfirmed size as well as periodic artificial selection of each outbred stock for fecundity (refs 11, 40, 47 and G. Pucak, J. Staats, J. Dorey, C. T. Hansen, personal communications). The following abbreviations were used: Jax: the Jackson Laboratories, Bar Harbor, Maine; RPMI: Roswell Park Memorial Institute, Buffalo, New York; NIH: NIH, Bethesda, Maryland; CRBL: Charles River Breeding Labs, Wilmington, Massachusetts; RI: Rockefeller Institute, New York, New York.

The genetic constitution of the three outbred mouse populations and six inbred derivative strains is presented for each locus in Table 1. Of the 46 loci tested, 37 (80.4%) were monomorphic in each population and, interestingly, for the same allele in all three colonies. Conversely, 9 of the 46 loci (19.6%) were polymorphic for at least two alleles in one or more of the three outbred colonies. Alternative alleles were found to be homozygous in different inbred strains at each of the polymorphic loci except *Gpt-1*. In addition, two of the loci which were invariant within the outbred colonies (*Es-3* and *Es-6*) were fixed for different alleles in derivative inbred strains. The finding of differential fixation for each polymorphic allele in different inbred derivatives is taken as evidence that the observed variation has a genetic basis, and that the present polymorphisms probably existed in and are thus derived from Lynch's original colony.

The allelic frequencies of each of the nine polymorphic loci in the three outbred mouse colonies are presented in Table 2. Six of the nine loci are polymorphic in all three populations, and three loci, *Gpi-1*, *Id-1* and *Got-2*, have become monomorphic or nearly so in at least one of the three colonies. The allelic frequencies were used to estimate the expected frequency of heterozygotes ($2pq$) for each population at each polymorphic locus[18–20] also presented in Table 2. Each locus was tested for conformity to the Hardy–Weinberg equilibrium (HWE) by a χ^2 test with one degree of freedom. Two departures from expectation for a random breeding population were observed: *Hbb* ($\chi^2 = 16.45$, $P \leq 0.0005$) and *Id-1* ($\chi^2 = 7.6$, $0.005 \leq P \leq 0.01$), both in the Eppley population. Similar distortions of *Hbb* genotypic frequencies have been reported in several wild mouse populations[21–24]. The conformity of 19 of 20 tested loci (excluding *Hbb*) to HWE effectively excludes any marked influence of assortive mating, heterosis, migration or selection on the operation of random mating in these populations. As HWE is a stable one (it depends on allele frequencies at the time of sampling and is independent of allele frequencies in previous generations), the sample frequencies give little indication of the randomness (or otherwise) of mating in the 50-yr history of Swiss strains.

Comparison of Swiss colonies to wild mouse populations

The proportion of polymorphic loci measured in the Swiss colonies and a number of feral mouse populations is presented in Table 3. Also presented for each population is the average heterozygosity, which is a better estimate of genic variation in random breeding populations because it takes gene frequencies into account. The Eppley colony is the most polymorphic of the Swiss mice, with 19.6% of its loci polymorphic, compared with 17.4% CD-1, and 13.4% N.NIH(s). The average, 16.8%, is not quite as high as the average calculated for the natural mouse populations listed in Table 3, including two California populations (Lake Casitas and Bouquet Canyon) which were tested for the same 46 loci[24]. The average heterozygosity of Swiss mice is 0.071, which is only slightly lower than the average heterozygosity calculated for the two California feral mouse populations tested for the same 46 loci (0.084) and previously published estimates for mice (Table 3). The values are also comparable to variability estimates of human populations reported by Harris and Hopkinson (0.067)[25] and Nei and Roychoudhury (0.10)[26].

The similarity between the three Swiss colonies and feral mice tested in this laboratory was quantitated using Nei's genetic distance[27,28] (Table 4). This statistic measures the degree of allelic substitution between populations based on electrophoretic mobility of several gene–enzyme systems. Within the limits of Nei's assumptions[27], the genetic distance estimates increase proportionately with the amount of time the populations have been reproductively isolated. The average distance between the three Swiss colonies is slight (0.023), approximately the same as the distance between the Lake Casitas and Bouquet Canyon (0.019) which are local populations separated by 40 miles in southern California[24]. The genetic distance between the Swiss mice and the California mice (average 0.062) is three times the distance within the two groups, indicating an isolation of Swiss from American mice three times longer than isolation within either group. This observation is consistent with the European origin of Swiss mice some 70 years ago.

The following enzymes were scored from mouse liver extracts: acid phosphatase (*Acp-1*), adenosine deaminase (*Ada*), glucose-6 phosphate dehydrogenase (*G6PD*); from red blood cell lysates: esterase-3 (*Es-3*), esterase-10 (*Es-10*), glucose phosphate isomerase (*Gpi-1*), haemoglobin α, β chain (*Hbα*, *Hbb*), phosphoglucomutase-1 and -2 (*Pgm-1* and *Pgm-2*); from serum: esterase-5 (*Es-5*), esterase-s (*Es-s*); from kidney: adenine phosphoribosyl transferase (*Aprt*), adenylate kinase-1 (*Ak-1*), adenylate kinase-2 (*Ak-2*), alcohol dehydrogenase (*Adh*), esterase-1 (*Es-1*), esterase-2 (*Es-2*), esterase-6 (*Es-6*), glutamate oxaloacetate transaminase(soluble) (*Got-1*), glutamate oxaloacetate transaminase(mitochondrial) (*Got-2*), glutamate pyruvate transaminase(soluble) (*Gpt-1*), glyceraldehyde 3-phosphate dehydrogenase (*Gapdh*), glutathione reductase (*Gr-1*), glyoxylase (*Glo-1*), hexokinase (*Hk-1*), hypoxanthine phosphoribosyl transferase (*Hprt*), isocitrate dehydrogenase(soluble) (*Id-1*), isocitrate dehydrogenase(mitochondrial) (*Id-2*), lactate dehydrogenase-A (*Ldh-1*), lactate dehydrogenase-B (*Ldh-2*), malate dehydrogenase(mitochondrial) (*Mor-1*), malate dehydrogenase(soluble) (*Mor-2*), malic enzyme(mitochondrial) (*Mod-2*), malic enzyme(soluble) (*Mod-1*), mannose phosphate isomerase (*Mpi-1*), purine nucleoside phosphorylase (*Np-1*), peptidase-1 (*Pep-1*), peptidase-2 (*Pep-2*), peptidase-3 (*Pep-3*), peptidase-4 (*Pep-4*), peptidase-7 (*Pep-7*), 6-phosphogluconate dehydrogenase (*Pgd-1*), pyrophosphatase (*Pyp*), superoxide dismutase(soluble) (*Sod-1*), superoxide dismutase(mitochondrial) (*Sod-2*). The vertical starch gel electrophoresis apparatus (Buchler) was used in combination with 12% Electrostarch (Electrostarch) for each system except adenosine and hypoxanthine–guanine–phosphoribosyl transferase. These systems were assayed following electrophoresis in 7% acrylamide in an EC-Apparatus (E.C. Apparatus). Phosphoribosyl transferases were detected by incubation of the gels with ^{14}C-labelled substrates. The phosphorylated products were precipitated with $LaCl_3$, and the gels were dried and exposed to autoradiography[41]. Haemoglobin was separated in gels containing 0.8% cystamine dihydrochloride[42]. The remaining enzymes examined were separated and visualised by modifications of standard isozyme procedures[43–45]. A = no name assigned to this allele. Numbers in parentheses after gene symbol are chromosome assignments.

$2pq$ is the predicted frequency of heterozygotes based on allele frequencies. HWE χ^2 is the value obtained in testing conformity of observed phenotype frequencies to those expected in conditions of Hardy–Weinburg equilibrium.

The Swiss outbred mouse polymorphisms are not qualitatively different from those reported for wild mouse populations[29–32]. Eight of the nine polymorphic loci (excluding *Glo-1*)[33] seen in Swiss outbred mice vary between inbred strains[15–17] and in wild mouse surveys. Of the 37 gene–enzyme systems which are monomorphic in Swiss outbred mice, 9 (*Es-1, Es-2, Es-3, Es-5, Mor-1, Pep-2, Pgd-1, Pgm-2* and *Sod-1*) were polymorphic in at least one natural population previously studied, but only 3 (*Es-2, Es-3, Pep-2*) were polymorphic in the majority of the natural populations sampled[23,29–32]. The other gene enzyme systems were either monomorphic or never tested in natural populations.

Have the Swiss colonies been supplemented by non-Swiss mice?

It is, unfortunately, impossible to determine whether or not any of the Swiss stocks has been contaminated with non-Swiss mice during their history. Our data do, however, strongly suggest that migration from non-Swiss mice significant enough to change the genetic constitution of the stock has not occurred in any of the three colonies. First, the genetic distance (Table 4) between the colonies is small and approaches the limits of population identity provided by this statistic[27,28]. The inter-colony distances are lower than 140, distances calculated between 18 different feral mice populations previously studied (S. J. O'Brien, in preparation). Second, two of the loci which were polymorphic in Swiss mice, *Gpi-1* and *Pgm-1*, are monomorphic in American populations[24,29], where the colonies developed, and polymorphic in European mice, the purported founders of Swiss mice. Third, *Glo-1* is monomorphic in wild mice[24], and between all inbred strains (excluding HSFR and MA/MyJ, Swiss derivatives[33]), but is polymorphic at appreciable frequencies in each of the Swiss colonies. Fourth, the Swiss inbred strains (Table 1) are fixed for each of the different alleles at each locus polymorphic in the outbred colonies. These genetic distributions are characteristic of each colony and thereby emphasise their consanguinity with each other and their distinctiveness from other mouse populations which might have been a source of migrating genes.

Swiss mice as an island population

The Swiss mouse has been isolated from its natural environment for over 50 yr (approximately 175 generations) and the colonies studied have been separated for over 30 yr (~ 122 generations). If, as claimed by their keepers, they have not been supplemented by non-Swiss mice during this period, they can be considered as characteristic island populations[34], isolated from migration and the selective rigours of the wild state. The retention of considerable genic variability comparable to that of mainland populations has been observed in feral mice in Hawaii[21] and Skokholm Island off the British mainland[31,32], and in six island populations of *Drosophila willistoni* in the West Indies[35]. In addition, at least one laboratory population of *Drosophila melanogaster* retained levels of polymorphism nearly identical to those of wild populations after laboratory propagation for over 20 yr (520 generations)[36].

The slight loss in genetic variance we observe here compared with wild mice or previous variability in Swiss populations indicated by variant inbred mice at two additional (to presently polymorphic) loci is probably due to genetic drift. The following calculation tends to support this notion. To estimate the rate of lost variation due to drift in isolated populations, Fisher[37] and Wallace[38] derived the equation

$$H_t = H_0 e^{-t/2N}$$

where H_t is the proportion of heterozygotes at generation t, H_0 is the proportion of heterozygotes at generation 0, and N is the effective breeding size of the population. We can estimate the minimum average breeding size (N) of the three colonies which would result in the observed average heterozygosity by estimating H_0 from data for either inbred mice or wild mice as a norm over 175 (+) generations in the laboratory. If $H_0 = 0.12$ (assuming 11/46 heterozygous loci originally, at a maximum heterozygosity of 0.5 at each locus), then $N = 118$ for N.NIH(s), 154 for CD-1 and 293 for Eppley. If we use $H_0 = 0.10$ (from the highest mouse population, Lake Casitas, in Table 3), the N values become 138 for NIH(s), 201 for CD-1 and 665 for Eppley. Thus, one would expect the average heterozygosity seen in the Swiss mice from genetic drift alone if their breeding sizes approximated the calculated values. With smaller breeding sizes the genetic variance would be less than we observe. The actual breeding sizes of the colonies are clearly well within these predicted ranges. In fact, one generation bottlenecks (for example, Lynch's original transport or caesarian rederivations of Swiss mice) of as few as 10 mice would have resulted in the loss of less than 10% of the included variation[39]. From these considerations, the possibility of inbreeding (conscious or not) to the extent of significantly diminishing the genetic variance of Swiss mice is unlikely.

Conclusions

The results of this survey of three isolated colonies of Swiss mice indicate that a considerable amount of genetic variation persists in the stock. The average heterozygosity of Swiss mice (0.07) is very similar to estimates for feral mouse[24,29–32] and human[25,26] populations. Sampling of six inbred mouse strains derived at different periods in the history of Swiss mice provided the equivalent of fixed gametic samples from the generation of origin of the inbred line. The inbred samplings reinforce the age and persistence of the presently observed polymorphisms and indicate the existence of variability at two loci now monomorphic in Swiss mice. The population structure of the three colonies today is consistent with prior fixation at these loci due to genetic drift, possibly during population bottlenecks or short periods of inbreeding[11,40]. The populations today appear to be functionally random bred insofar as their genotype frequencies distribute as a bionomal Hardy–Weinberg equilibrium.

With respect to the three questions posed at the outset, the data are quite specific: (1) The three Swiss colonies are quite similar to each other in the extent and character of their included genic variation. The genetic distance between colonies is low, as would be predicted of populations separated for a few hundred generations. (2) The Swiss mice contain slightly less variation than do wild mouse populations, but the similarities to feral populations are more apparent than the differences. (3) The alleles observed, both monomorphic and polymorphic, are for the most part the same ones found in wild populations.

With reference to the question of efficacy of using outbred mice in carcinogenesis and toxicology protocols, the data presented here are precise, although specifically limited. The Swiss mouse colonies do seem to provide a realistic model of isolated outbred mouse populations in terms of persistence of genetic variation. If one chooses to test outbred animals, these colonies will suffice. Thus, the argument that random-bred laboratory strains are probably inbred seems to be incorrect. Nevertheless, the decision to use outbred as opposed to inbred animals for testing protocols must ultimately be made on the basis of the information desired from the individual test, considerations which are beyond the scope of this report.

Table 4 Genetic distance (D) and identity (I) estimates of Swiss and wild mouse populations

	I				
D	Lake Casitas	Bouquet Canyon	N.NIH(s)	CD$_1$	Eppley
Lake Casitas		0.981	0.928	0.939	0.969
Bouquet Canyon	0.019		0.922	0.931	0.949

Eppley	0.032	0.052	0.025	0.020	

I equals the probability of allelic identity of any randomly selected genes at any locus in each of two test populations. D equals the average number of gene differences per locus between individuals from the two test populations. Algebraically

$$I = J_{xy}/\sqrt{J_x J_y}$$

$$D = -\ln I$$

where J_{xy} is the arithmetic mean of $j_{xy} = \sum_i x_i y_i$ over all loci, J_x is the arithmetic mean of $j_x = \sum_i x_i^2$ over all loci, and x_i (or y_i) is the frequency of the ith allele in the first (or second) population[28].

Transglutaminase is essential in receptor-mediated endocytosis of α_2-macroglobulin and polypeptide hormones

Peter J. A. Davies, Dana R. Davies, Alexander Levitzki*, Frederick R. Maxfield, Pierre Milhaud, Mark C. Willingham & Ira H. Pastan

Laboratory of Molecular Biology, National Cancer Institute, National Institutes of Health, Bethesda, Maryland 20205

The receptor-mediated endocytosis of α_2-macroglobulin can be inhibited by a diverse group of chemical compounds all of which share the property of being inhibitors of one form of cellular transglutaminase. The present results strongly suggest that protein cross-linking may be essential for receptor-mediated endocytosis of some protein and polypeptide hormones.

RECEPTOR-mediated endocytosis is the process by which cells bind and internalise specific extracellular ligands. The process is responsible for the uptake of a variety of proteins and peptides, including the serum proteins low density lipoprotein (LDL)[1] and α_2-macroglobulin (α_2M)[2–5], several lysosomal hydrolases[6,7] and the polypeptide hormones insulin and epidermal growth factor (EGF)[8–12]. For several of the ligands, ultrastructural studies have shown that internalisation occurs over clathrin-coated regions of the membrane[1,4,11,12]. The internalisation of α_2M follows the same pathway as the internalisation of insulin and EGF[2]; unoccupied receptors are diffusely distributed on the cell surface of cultured fibroblasts and cluster over clathrin-coated pits after the ligand binds[2,8,10]. LDL receptors, on the other hand, seem to be concentrated over coated regions even in the absence of ligand binding[1]. These coated regions pinch off to form endocytotic vesicles which transfer the internalised ligands to other organelles.

Although the steps involved in receptor-mediated endocytosis have been described, the molecular mechanisms involved in the process are unknown. To understand the mechanism of ligand internalisation we have searched for inhibitors of receptor-mediated endocytosis. Recently, we have observed that the first step in the process, the aggregation of ligand–receptor complexes over coated pits, required extracellular Ca^{2+} and was inhibited by primary alkylamines[13]. This observation suggested several potential mechanisms of inhibition, including the possibility that a transglutaminase might be important in the process. Transglutaminase is an intracellular enzyme found in many types of cells. Some transglutaminases covalently cross-link proteins by forming ε-(γ-glutaminyl)-lysine cross-bridges (for review see ref. 14). These enzymes require Ca^{2+} for activity and can be inhibited by a variety of primary amines. Several forms of transglutaminase are known. Guinea pig liver transglutaminase and plasma transglutaminase have been purified, and a wide variety of specific inhibitors of these enzymes have been identified[14–16].

To test the hypothesis that a transglutaminase is involved in receptor-mediated endocytosis, we tested a wide variety of inhibitors of transglutaminases to see if they blocked ligand clustering and internalisation. We have found an excellent correlation between the ability of compounds to inhibit a

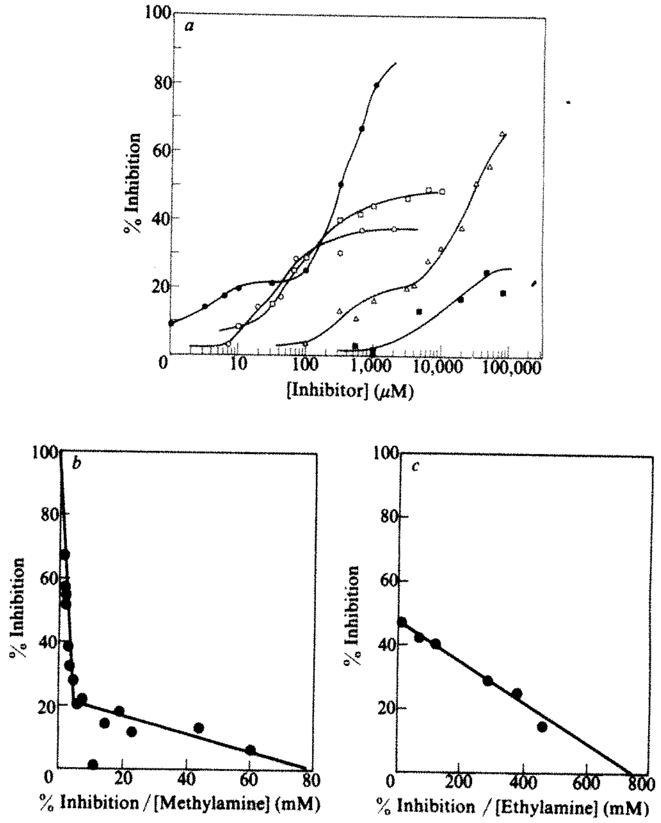

Fig. 1 Inhibition of transglutaminase in CHO extracts. *a*, log dose–response curves for inhibition of CHO transglutaminase by dansylcadaverine (●), ethylamine (□), bacitracin (○), methylamine (△) and tolbutamide (■). *b*, Plot of fractional inhibition against fractional inhibition/inhibitor concentration (Eadie–Hofstee) for methylamine on CHO transglutaminase. *c*, As (*b*) but for ethylamine. CHO cells were grown in suspension culture in Dulbecco's modified essential media (DMEM) containing 10% heated calf serum to a density of 1 × 10^6 cells per ml. Cells were pelleted, washed twice in phosphate-buffered normal saline (PBS), resuspended to 1–4 mg cell protein per ml in PBS and lysed by sonication. Extracts were frozen at −70 °C and then thawed and assayed for transglutaminase activity. Assays measured the Ca^{2+}-dependent incorporation of ^{3}H-putrescine into casein using a filter paper assay[18]. The assay mixture (200 μl) contained 20 mM Tris-HCl, *p*H 7.4, 2 mg ml^{-1} casein (Mann), 5 mM mercaptoethanol, 5 mM ^{3}H-putrescine (40 c.p.m. pmol^{-1} NEN) and various concentrations of inhibitor. All inhibitors were adjusted to *p*H 7.4 before addition to the assay. The reaction was initiated by addition of ^{3}H-putrescine and incubation at 37 °C and duplicate aliquots (25 μl) were taken at 3 and 6 min, spotted on filter papers (Whatman 3MM) and precipitated by addition to cold 10% trichloroacetic acid. After washing, dehydrating and drying[18], filters were counted in a toluene-based scintillation cocktail (Econofluor, NEN) at an efficiency of 13%. The background activity measured in the absence of Ca^{2+} (5 mM EGTA) was 50–150 c.p.m. and was subtracted from all values. Enzyme activity varied over 4–10 nmol putrescine incorporated per min per mg cell protein, depending on the preparation used. Data shown represent means of duplicate determinations pooled from at least two separate experiments.

fibroblast transglutaminase and their ability to inhibit the aggregation and internalisation of α_2M. It therefore seems possible that protein cross-linking is essential for the endocytosis of hormones and α_2-macroglobulin.

Inhibition of fibroblast transglutaminase

Transglutaminase activity in fibroblasts was assayed by measuring Ca^{2+}-dependent covalent incorporation of ^{3}H-putrescine into casein[17,18]. Transglutaminase activity (4–10 nmol per min per mg cell protein) was 10–20 times higher in extracts of CHO cells than in normal rat kidney (NRK) fibroblasts or BALB 3T3 fibroblasts. Therefore, we used CHO extracts to characterise inhibitors of fibroblast transglutaminase.

We first examined methylamine as an inhibitor of CHO transglutaminase. As shown in Fig. 1*a*, low concentrations of methylamine produced partial inhibition of CHO transglutaminase activity but much higher concentrations were required to produce complete inhibition. Kinetic analysis of the inhibition curve (Fig. 1*b*) showed that the inhibition consisted of two components. A high-affinity component (K_i 0.2 mM) accounted for 25% of the total activity, and a low-affinity component (K_i 20 mM) accounted for the remainder. The fraction of high-affinity component varied from 25 to 50% total activity depending on the preparation of cells used. Similar results were obtained with other fibroblast cell lines, NRK and BALB 3T3, but because of the low specific activity and a lower fraction of the high-affinity transglutaminase pool, quantitative measurements were difficult.

Ethylamine was more potent than methylamine (Fig. 1*a*), but even high concentrations produced only partial inhibition of transglutaminase activity. Kinetic analysis of the ethylamine inhibition curve (Fig. 1*c*) showed a straight line, indicating a single component of inhibition, with K_i 35 μM, that accounted for 45% of the total enzyme activity. *n*-Propylamine, isopropylamine and *n*-hexylamine were all equivalent to ethylamine as inhibitors of CHO transglutaminase (data not shown).

Dansylcadaverine, a very potent inhibitor of liver and serum transglutaminases[16,19], is also a potent inhibitor of CHO transglutaminase (Fig. 1*a*). Concentrations of 1–100 μM produced partial inhibition of the enzyme activity whereas higher concentrations produced complete inhibition. As with methylamine, kinetic analysis demonstrated two components of inhibition, a high-affinity component (K_i 2.5 μM, 28% total activity) and a low-affinity component (K_i 200 μM, 72% of total activity).

We have also identified two novel inhibitors of CHO transglutaminase activity, the peptide antibiotic, bacitracin, which blocks hormone degradation[20] and the sulphonylurea, tolbutamide. As shown in Fig. 1*a*, both produced partial inhibition of CHO transglutaminase; bacitracin had a K_i comparable to that of ethylamine, 35 μM. Tolbutamide was much less active, the K_i being approximately 2 mM.

Dansylcadaverine inhibition of receptor-mediated endocytosis in CHO cells

α_2-Macroglobulin binds to saturable cell-surface receptors[5]. As shown in Table 1, rhodamine-labelled α_2M (R-α_2M) retains the ability to bind to these receptors. The bound α_2M becomes concentrated over clathrin-coated pits[4] and is internalised in endocytotic vesicles[21].

As the biochemical studies on transglutaminase were carried out in CHO cell extracts, we also characterised the clustering and internalisation of α_2M by these cells. The experimental protocol was similar to that reported by Maxfield *et al.*[13]. CHO cells in serum-free culture media were exposed to R-α_2M for 30 min at 37 °C. Unbound R-α_2M was then removed and the cells were washed and fixed with formaldehyde. The bound R-α_2M was viewed in an epifluorescence microscope using a silicon intensifier television camera[22]. Data presented are photographs of a video monitor.

Figure 2 shows receptor-mediated endocytosis of R-α_2M by CHO cells and the effect of dansylcadaverine on the process. Figure 2*a* shows the punctuate pattern of fluorescence which is seen after a 30-min incubation with R-α_2M at 37 °C. This pattern represents the result of the clustering and internalisation of the R-α_2M. The dashed lines denote the margins of individual cells.

Table 1 Fluorescence intensities of NRK cells incubated with rhodamine-α_2-macroglobulin

Incubation conditions	Fluorescence intensity (arbitrary units)
R-α_2M (10 μg ml^{-1})	4±2
R-α_2M (30 μg ml^{-1})	18±6
R-α_2M (100 μg ml^{-1})	57±16
R-α_2M (300 μg ml^{-1})	95±20
R-α_2M(100 μg ml^{-1})+α_2M (2 mg ml^{-1})*	9±4
Dansylcadaverine (50 μM), 30 min; R-α_2M (100 μg ml^{-1})†	43±12
SFM, 30 min; R-α_2M (100 μg ml^{-1})†	48±15

NRK cells were plated on Falcon tissue culture dishes and grown to confluency. The cells were rinsed with serum-free medium (SFM) and incubated with the indicated concentrations of R-α_2M in SFM for 30 min at 37 °C. Cells were rinsed, fixed and observed as described in Fig. 2 legend. Clusters were observed at all concentrations of R-α_2M tested. For intensity measurements, an EMI 9658 R photomultiplier tube was mounted on the microscope, and the incident illumination was passed through a monochromator (Instruments SA, model H10) with a spectral bandpass of 8 nm in addition to the narrow bandpass filter on the microscope. The diameter of the illumination beam was approximately 30 μm in the focal plane. The values shown are the mean and standard deviation of the intensities at 20 randomly selected locations on the dish. Untreated cells had an intensity of 5 units and this was subtracted from all the values shown. Duplicate dishes gave the same average value ±10%. Similar results were obtained with CHO cells. Trypsin treatment of the R-α_2M to form trypsin-α_2M complexes[5] did not significantly alter the binding.

* α_2M was added to the cultures 5 min before R-α_2M.

† Dansylcadaverine was added 30 min before R-α_2M; control dishes were incubated with SFM.

As can be seen in Fig. 2*b*, cells treated with 20 μM dansylcadaverine show a marked reduction in the number and intensity of fluorescent spots. There is a compensating increase in diffusely distributed fluorescence. The effect is more marked with 100 μM dansylcadaverine (Fig. 2*c*). Few clusters are seen and R-α_2M seems to be diffusely distributed on the cell surface. By titration it is possible to estimate roughly the concentration of inhibitor required to produce a 50% decrease in the number and intensity of fluorescent spots (ID_{50}). Concentrations three- to fivefold below the ID_{50} produced no observable effect. Concentrations near the ID_{50} partially inhibited clustering (Fig. 2*b*), and concentrations three- to fivefold higher than the ID_{50} almost completely blocked clustering (Fig. 2*c*). In the case of dansylcadaverine, we estimated an ID_{50} of 20 μM. The effect of dansylcadaverine was not unique to CHO cells. Equivalent concentrations of dansylcadaverine blocked clustering and internalisation of R-α_2M in NRK cells and Swiss 3T3 fibroblasts (data not shown). Dansylcadaverine was also equally effective in inhibiting the clustering of rhodamine-conjugated EGF on NRK cells (Fig. 2*e, f*) and on Swiss 3T3 cells (data not shown).

To rule out an effect of dansylcadaverine on R-α_2M binding, CHO cells were incubated for 30 min with dansylcadaverine and then for 15 min more with added R-α_2M. Both unbound R-α_2M and dansylcadaverine were then washed out and the fate of the diffusely bound R-α_2M was followed (Fig. 2*d*). Within 30 min, bright fluorescent spots formed, indicating that ligand previously bound to receptor was competent to cluster and be internalised. Dansylcadaverine did not significantly affect the fluorescent intensity of cells incubated with R-α_2M (Table 1). Furthermore, dansylcadaverine did not reduce the binding of ^{125}I-EGF by cells (H. Haigler and I.H.P., in preparation).

Correlation of inhibition of clustering with inhibition of transglutaminase

Having established conditions for assaying inhibition of transglutaminase and also inhibition of receptor-mediated endocytosis, we compared the potency of various compounds as inhibitors of the two processes. The results are plotted in Fig. 3. The data obtained with CHO cells are shown by solid circles;

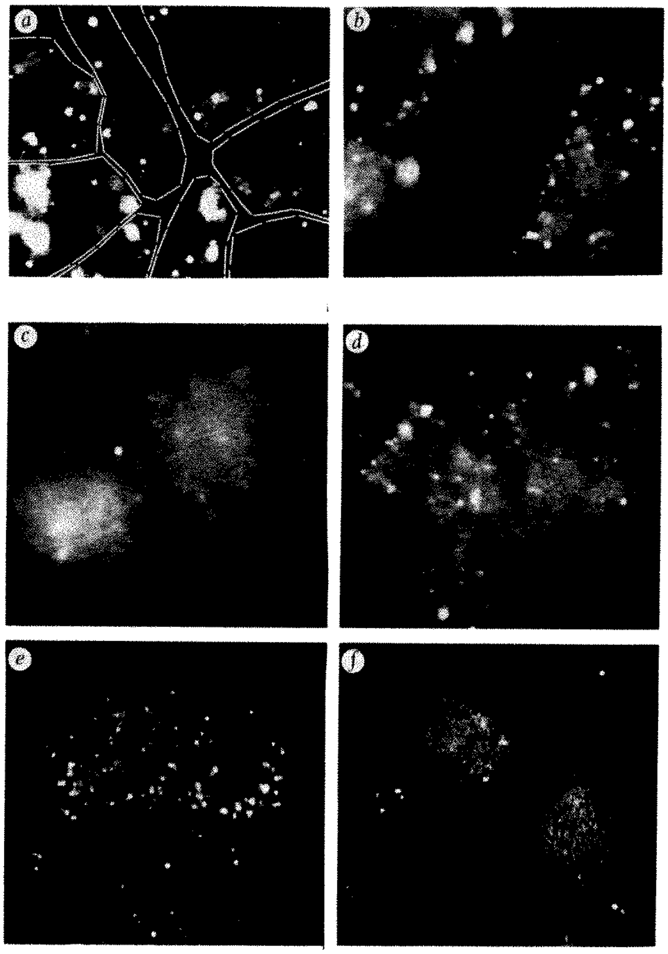

Fig. 2 Effect of dansylcadaverine on R-α_2M and EGF clustering by CHO and NRK cells. *a*, R-α_2M distribution at 37 °C. Fluorescent spots indicate clustered R-α_2M on the cell surface and internalised fluorescent endocytotic vesicles. Dashed line shows outline of individual cell. *b*, R-α_2M + 20 μm dansylcadaverine; *c*, R-α_2M + 100 μM dansylcadaverine; *d*, R-α_2M + 100 μM dansylcadaverine followed by washout of unbound R-α_2M and dansylcadaverine; *e*, NRK cell + rhodamine-lactalbumin-EGF (R-lac-EGF); *f*, NRK + *R*-lac-EGF + 40 μM dansylcadaverine. CHO cells were plated on Falcon tissue culture dishes and grown for 48 h to confluency in DMEM plus 10% heated calf serum. Dishes were rinsed three times with 37 °C DMEM, and preincubated for 30 min at 37 °C in DMEM with or without dansylcadaverine. After preincubation, 20 μl of R-α_2M (6 mg ml^{-1} in PBS) was added and the incubation continued for 30 min at 37 °C. Normal rat kidney cells (NRK) were treated in the same fashion except that R-lac-EGF[13] (100 ng ml^{-1}) was added. After incubation the media were removed and the dishes rinsed three times with 37 °C DMEM and then fixed for 5 min in 2% formaldehyde in PBS at room temperature. Fixative was removed, the dishes rinsed twice with PBS and then fluorescence examined by epifluorescence illumination in a Zeiss RA microscope equipped with a RCA 1030H silicon intensifier television camera. The fluorescence image on the video monitor was directly photographed using a Polaroid camera. In panel *d*, after incubation with R-α_2M, dishes were rinsed four times with DMEM and then incubated for 30 min at 37 °C in DMEM before fixation. All magnifications ×1,467.

compounds assayed in permeabilised NRK cells, shown by solid squares, will be discussed in the following section. For transglutaminase inhibitors with two components in the inhibition curve, the value of K_i for the high-affinity site was used.

The most potent inhibitor of CHO transglutaminase tested was dansylcadaverine, with a K_i for the high-affinity site of 2.5 μM. As discussed above, 20 μM dansylcadaverine produced a 50% inhibition of R-α_2M clustering (Fig. 3, no. 1). Methylamine was much less effective than dansylcadaverine in inhibiting transglutaminase, with a K_i for the high-affinity site of 0.2 mM; high concentrations of methylamine (10 mM) were required to inhibit clustering (Fig. 3, no. 2). Ethylamine was more potent than methylamine both in the transglutaminase assay and as an inhibitor of clustering (ID_{50} 2 mM) (Fig. 3, no. 3). *n*-Propylamine, isopropylamine and *n*-hexylamine, all of which were equivalent to ethylamine as inhibitors of CHO transglutaminase, were also equivalent in terms of their ability to block R-α_2M clustering and internalisation. Finally, both the novel inhibitors of transglutaminase, bacitracin and tolbutamide, inhibited R-α_2M clustering. Bacitracin (Fig. 3, no. 4) was quite a potent inhibitor, with an ID_{50} of approximately 350 μM. Bacitracin was effective as an inhibitor of α_2M clustering in intact CHO, NRK and Swiss 3T3 cells. The oral hypoglycaemic agent, tolbutamide, blocked α_2M clustering. In line with its low affinity for transglutaminase, quite high concentrations of tolbutamide were required to inhibit clustering; the ID_{50} was 20 mM (Fig. 3, no. 5). There was a clear correlation between the activity of compounds as inhibitors of CHO transglutaminase and their ability to inhibit the aggregation and internalisation of α_2M by CHO cells.

Inhibition of clustering in permeabilised NRK cells

The studies of inhibitors of CHO transglutaminase demonstrated a quantitative correlation between inhibition of the enzyme and inhibition of clustering. However, the inhibitors tested were all compounds capable of diffusing into cells. To examine a wider range of transglutaminase inhibitors, we treated cells with 10% dimethyl sulphoxide (DMSO). In these conditions, cells became permeable to low molecular weight compounds (as judged by a loss of Trypan blue exclusion) but retained the capacity to bind and cluster R-α_2M. These studies were carried out with NRK cells because they adhered to the substratum well enough to permit permeabilisation without detachment of cells.

The requirement for permeabilisation is demonstrated by the studies of putrescine inhibition of clustering (Fig. 4*a–c*). Putrescine is a good substrate for NRK transglutaminase (K_m 8.5 mM). However, it does not readily diffuse into cells[23]. Figure 4*a* shows R-α_2M aggregation in permeabilised cells; clusters of fluorescent ligand are seen. Figure 4*b*, *c* shows that, whereas in an intact cell even 100 mM putrescine does not block clustering, in a permeabilised cell, 20 mM putrescine is sufficient to block R-α_2M clustering.

The development of a permeabilised cell model for receptor-mediated endocytosis allowed us to assay peptide inhibitors of transglutaminase. Liver transglutaminase is inhibited by a variety of lysyl peptides[15] of which *N*-acetyl-L-lysine-*O*-methyl ester is one of the more effective (K_i 0.5 mM). This ester also blocked R-α_2M clustering in permeabilised NRK cells, but it was ineffective in intact NRK cells. The correlation of the ID_{50} (4 mM) in NRK cells and the K_i is shown in Fig. 3, no. 7. Another transglutaminase substrate tested was the glutaminyl peptide, carbobenzoxy-glutaminyl-glycine. This inhibitor differed from other inhibitors tested as it competes for the glutaminyl binding site on transglutaminase. The compound is a weak inhibitor of liver transglutaminase (K_i 7.5 mM)[14] and also a weak inhibitor of R-α_2M clustering (ID_{50} 2 mM). This relationship is shown in Fig. 3, no. 9.

Another type of inhibitor tested was an irreversible site-specific inhibitor of transglutaminase, carbobenzoxy-diazonorvaline-paranitrophenyl ester (Z-DONVPA) (J. Folk, personal communication). Intact NRK cells were preincubated for 15 min at 37 °C with Z-DONVPA and then washed extensively

Table 2 Effect of cell density on α_2M clustering and transglutaminase activity in CHO cells

	Fluorescent clusters per cell (mean ± s.d.)	
Cell density	Control	+10 mM methylamine
Low (0.2 × 10^5 cells cm^{-2})	9.9 ± 5.1	<1
High (1.5 × 10^5 cells cm^{-2})	27.5 ± 11.2	6.9 ± 4.2

CHO cells were treated with R-α_2M (100 μg ml^{-1}) in conditions described in Fig. 1 legend. The total number of bright fluorescent spots associated with each was determined by focusing through the entire cell and counting the spots on a video monitor.

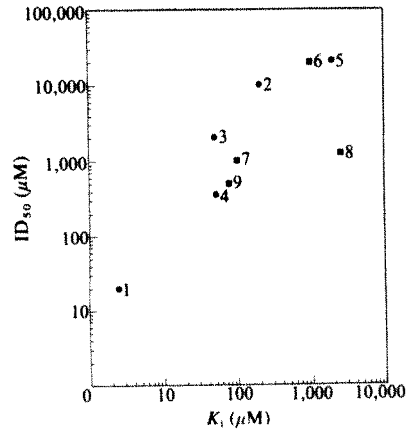

Fig. 3 Correlation between inhibition of transglutaminase and inhibition of α_2-M clustering. Compounds tested were: 1, dansylcadaverine; 2, methylamine; 3, ethylamine, *n*-propylamine, isopropylamine, *n*-hexylamine; 4, bacitracin; 5, tolbutamide; 6, putrescine; 7, *N*-acetyl-lysyl-*O*-methyl ester; 8, *N*-acetyl-(glycyl)$_2$-L-leucyl-L-lysyl-(glycyl)$_2$-glycine; 9, carbobenzoxy-glutaminyl-glycine. ●, Compounds assayed for inhibition of clustering and inhibition of-transglutaminase in CHO cells. The ID$_{50}$ was estimated as the concentration required to produce a 50% decrease in the number and intensity of fluorescent spots and is reproducible within a factor of 2. The K_i was calculated from the formula

$$K_i = \frac{[I]_{0.5}}{1 + (S/K_s)}$$

where $[I]_{0.5}$ was the concentration of inhibitor required to produce a 50% maximal inhibition of enzyme activity. The $[I]_{0.5}$ was derived from the slope of the Eadie–Hofstee plots as shown in Fig. 1*b*, *c*. For dansylcadaverine and methylamine the $[I]_{0.5}$ of the high-affinity component was used. S was the concentration of putrescine in the assay and K_s the Michaelis constant for putrescine; ■, compounds assayed for inhibition of clustering in permeabilised NRK cells (see Fig. 4 legend), K_i value reported for liver transglutaminase[14,15]. Linear regression analysis of the data gave a slope of 0.86, a *y* intercept of 1.3 and a correlation coefficient 0.83. The probability that this correlation was due to chance alone was <0.05.

before being exposed to R-α_2M. Z-DONVPA, 36 μM, in the preincubation step produced complete and irreversible inhibition of R-α_2M clustering.

Stereospecificity of inhibition of α_2M clustering

Folk and his colleagues have synthesised a heptapeptide model substrate of guinea pig liver transglutaminase, acetyl-(glycyl)$_2$-L-leucyl-L-lysyl-(glycyl)$_2$-glycine and have reported a K_i for this compound of 0.08 mM (ref. 15). As shown in Fig. 4*d* low concentrations of this peptide effectively inhibit R-α_2M clustering in permeabilised NRK cells. The ID$_{50}$ for the heptapeptide was estimated to be 0.5 mM (Fig. 3, no. 8). Stereoisomers of the heptapeptide containing either D-lysine (L, D-heptapeptide) or D-leucine and D-lysine (D,D-heptapeptide) are much less active than the L-leucine,L-lysine (L,L-heptapeptide) derivative[15]. As shown in Fig. 4*e*, 1.5 mM D,D-heptapeptide produced no inhibition of R-α_2M clustering. At 8 mM, D,D-heptapeptide was roughly equivalent to 1.5 mM of the L,L derivative (Fig. 4*f*). The L,D-heptapeptide was comparable to the D,D stereoisomer (data not shown). Thus, the sterospecificity of the inhibition of α_2M clustering matches the stereospecificity of guinea pig liver transglutaminase inhibition.

Effects of cell density on R-α_2M clustering

During these studies, it was noted that CHO cells at low cell densities did not produce many fluorescent clusters when exposed to R-α_2M, whereas dense cultures produced many clusters. Birckbichler has reported that the transglutaminase activity of WI-38 fibroblasts rises at confluency[24], and we have noted a precipitous rise in enzyme activity as CHO cells approach confluency. Table 2 compares the number of fluorescent clusters per cell in low cell density and high cell density CHO cells. Confluent cells cluster and internalise α_2M much more efficiently than low density cells. These cells also have much higher transglutaminase levels than low density cells[25]. We do not know if the increase in clustering is directly related to the increased transglutaminase activity, but it is consistent with that interpretation.

Discussion

These studies were undertaken to test the hypothesis that a transglutaminase is involved in receptor-mediated endocytosis of polypeptide hormones and α_2-macroglobulin. The approach was to see if a correlation could be made between the inhibition of transglutaminase and inhibition of the clustering and internalisation of α_2M. Figure 3 clearly demonstrates a remarkable concordance between inhibitors of transglutaminase and inhibitors of α-$_2$M clustering. The inhibitors range in potency over three orders of magnitude and include compounds as diverse as alkyl amines and diamines, lysyl peptides, a glutaminyl peptide, a peptide antibiotic and a sulphonylurea. Linear regression analysis of the data in Fig. 3 gives a slope to the regression line of 0.86, a correlation coefficient of 0.83 and a probability that the two variables are independently distributed of $P < 0.05$. The specificity of the correlation is clearly seen in the comparison of the stereospecificity of the two processes. A heptapeptide containing L-leucine and L-lysine inhibits both transglutaminase activity and R-α_2M clustering much more effectively than do the equivalent L,D or D,D stereoisomers. These observations indicate that it is very likely that a transglutaminase is required for the receptor-mediated endocytosis of certain ligands.

Several points have arisen from these studies. First, not all the transglutaminase activity in cell extracts is essential to hormone internalisation. Only the fraction of activity inhibited by low concentrations of dansylcadaverine, and by low concentrations of methylamine and other alkylamines seems to be related to receptor-mediated endocytosis. A major fraction of the transglutaminase activity in CHO cells was unaffected by most alkylamines, bacitracin or tolbutamide and could only be inhibited by high concentrations of dansylcadaverine or methylamine. These properties were unrelated to inhibition of α_2M clustering. On the basis of its susceptibility to inhibition, we believe the 'essential' transglutaminase activity resembles liver transglutaminase. The other form of the enzyme may be a modified form of liver transglutaminase, a proenzyme or a completely different enzyme. Fractionation of the activities will be required to resolve this question.

A second point is that 5–10 times more inhibitor was required consistently to produce a 50% inhibition of α_2M clustering than was required to produce a 50% inhibition of 'high-affinity' CHO transglutaminase. Several explanations may account for this discrepancy. It could be that 90% inhibition of ligand clustering and internalisation is only perceived as a 50% decrease in the number and intensity of fluorescent spots. Alternatively, 90% inhibition of enzyme activity may be required to interfere with ligand clustering at all. Another possible explanation is that the competition against endogenous substrates in the *in vivo* endocytosis assay may require higher concentrations of inhibitor than the competition against exogenous substrates in the *in vitro* transglutaminase assay. A fourth possibility, which we consider unlikely in view of the striking correlation in Fig. 3, is that receptor-mediated endocytosis requires an enzyme that is not transglutaminase but shares a very similar affinity for the wide variety of inhibitors tested. Although the discrepancies in ID$_{50}$ and K_i values cannot be ignored, we do not think they refute the demonstrated relationship between transglutaminase and endocytosis.

Another point which has developed from these studies concerns the location of the transglutaminase activity essential for α_2M aggregation. Inhibitors such as aliphatic amines or large aromatic molecules (such as dansylcadaverine) would be expected to diffuse readily into cells and these compounds were active in intact cells. Diamines and peptides, on the other hand, were active only after the cell had been permeabilised. This

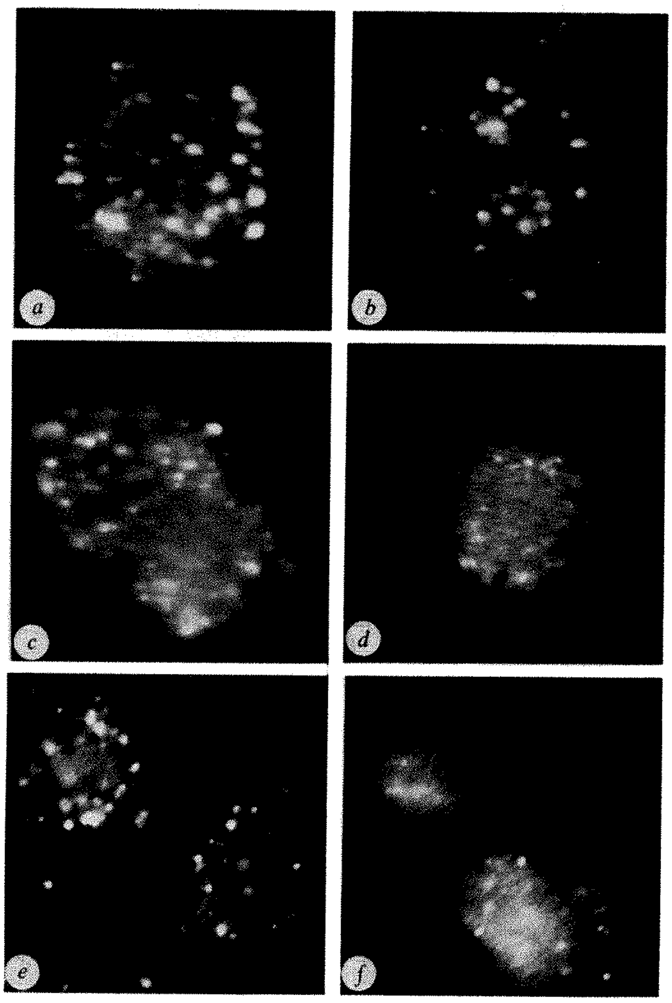

Fig. 4 Inhibition of R-α_2M clustering in permeabilised NRK cells, and effect of putrescine and stereoisomers of a lysyl peptide. *a*, R-α_2M clustering on permeabilised NRK cells; *b*, R-α_2M clustering in the presence of 100 mM putrescine on non-permeabilised NRK cells; *c*, inhibition of R-α_2M clustering by 20 mM putrescine on permeabilised NRK cells; *d*, inhibition of R-α_2M clustering by 1.5 mM acetyl-(glycyl)$_2$-L-leucyl-L-lysyl(glycyl)$_2$-glycine (L,L-isomer) on permeabilised NRK cells; *e*, R-α_2M clustering in the presence of 1.5 mM Ac-(glycyl)$_2$-D-leucyl-D-lysyl-(glycyl)$_2$-glycine (D,D-isomer) on permeabilised NRK cells, *f*, R-α_2M clustering in the presence of 8 mM Ac-(glycyl)$_2$-D-leucyl-D-lysyl-(glycyl)$_2$-glycine (D,D-isomer) on permeabilised NRK cells. Dishes containing normal rat kidney fibroblasts (NRK cells) were rinsed twice with DMEM at 37 °C containing 10% DMSO and then incubated at 37 °C for 30 min in the same media supplemented with inhibitor. The dishes were then gently rinsed twice with warm (37 °C) DMEM and incubated at 37 °C for 20 min in DMEM containing R-α_2M (40 μg ml^{-1}) and the same concentration of inhibitor as in the preincubation. Dishes were then washed, fixed and observed under epifluorescence illumination as described in Fig. 2 legend. All magnifications ×972.

observation suggests that the active transglutaminase is inside the plasma membrane. Furthermore, localisation with anti-guinea pig liver transglutaminase antibodies in 3T3 cells have shown that a cross-reactive antigen (presumably transglutaminase) is located close to the inner aspect of the plasma membrane in the submembrane microfilament mat[26]. Therefore, it seems likely that aggregation of cell-surface receptors somehow involves activity of an enzyme located on the cytoplasmic side of the membrane.

Figure 5 presents a model for receptor-mediated endocytosis which includes a possible role for transglutaminase. Unoccupied receptors for hormones and α_2M are diffusely distributed on the cell membrane. We suggest that in these conditions, transglutaminase in the cell is largely inactive because steady-state intracellular Ca^{2+} levels are far below the levels required for enzyme activity (0.1–1 mM)[27]. Following binding of ligand, occupied receptors may be altered so that they become associated in coated pits. We speculate that formation of small reversible aggregates in coated pits may promote local Ca^{2+} influx and local activation of transglutaminase. Recently, Novogrodsky *et al.*[28] have reported that the binding of concanavalin A to lymphocytes rapidly activates transglutaminase. The presence of activated transglutaminase, elevated Ca^{2+}, and aggregated ligand–receptor complexes might then result in covalent cross-linking of proteins in the complex. The proteins that might be cross-linked by such a reaction are not known. Receptors might be coupled to intrinsic membrane proteins or cytoskeletal proteins or coupled to each other. Recently, Baker *et al.*[29] and Linsley *et al.*[30] have reported covalent cross-linking of EGF, insulin and thrombin to their receptors during receptor-mediated endocytosis. The net effect of covalently cross-linking receptor proteins would be to make the aggregation process irreversible, and would result in a progressive accumulation of ligand–receptor complexes in the coated pit. Ultimately, the pit would pinch off and be internalised, resulting in the endocytosis of ligand–receptor complexes. The crucial step to confirming this hypothesis would be the identification of specific cross-linked proteins generated during receptor-mediated endocytosis.

This hypothetical scheme may not be applicable to all forms of receptor-mediated endocytosis or all routes of hormone internalisation. Some receptors, such as the LDL receptor, aggregate over coated pits even in the absence of ligand binding[1]. Protein cross-linking may not be required to stabilise these ligand–receptor complexes. In a human carcinoma cell line, A431, on the other hand, most EGF–receptor aggregates form over non-coated membrane and may be internalised by pinocytosis or by other mechanisms different from receptor-mediated endocytosis[11]. This form of hormone internalisation may not require transglutaminase activity. The biological significance of these different routes of endocytosis is not clear, but it is possible that cross-linking of proteins during internalisation may be of particular importance for receptor-mediated endocytosis that is coupled to receptor down-regulation.

In these studies, we have used pharmacological manipulation to alter some of the activities of transglutaminase in cells and have observed a concordant change in the ability to aggregate and internalise receptor-bound ligands. However, transglutaminase activity is under physiological control. As the data

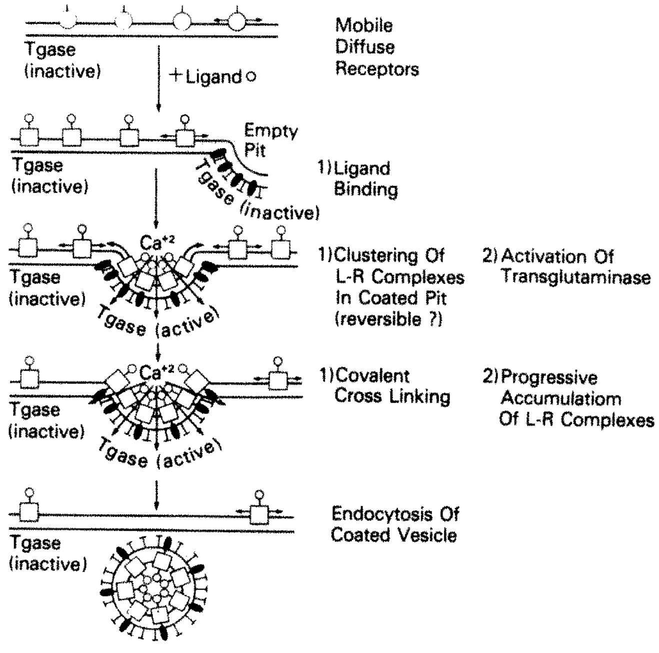

Fig. 5 Hypothetical model for receptor-mediated endocytosis of α_2M and polypeptide hormones. The steps in the model are described in the text. Tgase, transglutaminase.

in Table 2 demonstrate, changes in cell density are correlated with changes in ligand clustering and endocytosis. Transglutaminase activity in cells varies with cell density[24], with changes in intracellular cyclic AMP[25] and in response to viral transformation[24]. Such alterations in transglutaminase activity may be reflected in an alteration in the ability of cells to internalise surface-bound ligands. Maxfield *et al.*[31] have shown that blocking EGF internalisation with inhibitors of transglutaminase produced marked stimulation in the mitogenic response of cells to the hormone. Changes in transglutaminase activity may therefore profoundly modify the way that cells respond to hormones.

We thank Dr Jack Folk, NIH for the gift of various peptide inhibitors of transglutaminase and for stimulating discussions, Maria Gallo for preparing α_2-macroglobulin, and Elizabeth Lovelace for help with cultured cells. A.L. is on leave of absence from the Department of Biological Chemistry, the Hebrew University of Jerusalem, Israel.

Mapping of metabolites in whole animals by ^{31}P NMR using surface coils

Joseph J. H. Ackerman, Thomas H. Grove, Gordon G. Wong, David G. Gadian & George K. Radda

Department of Biochemistry, Oxford University, South Parks Road, Oxford, UK

The metabolic state of skeletal muscle and brain within intact rats is monitored using high resolution phosphorus nuclear magnetic resonance. Regional disturbances in metabolism (for example, localised ischaemia) are easily observed, indicating the diagnostic possibilities of the method. Measurements are made using 'surface' radiofrequency coils, which we discuss in detail.

IT was demonstrated in 1974 that phosphorus nuclear magnetic resonance (^{31}P NMR) can be used to observe the major phosphorus-containing metabolites in intact, excised muscle[1]. Since then the method, which is non-destructive, has been used to study a variety of biochemical, physiological and medical problems in skeletal muscle[2,3], heart[4,5], kidney[6], liver[7] and brain[8] (for reviews see refs 9–11). Apart from the measurements on mouse brain[8] and the recent experiments on heart in open-chested rats[12,13], all these studies were done on excised organs, albeit often in a physiologically functional state.

Recently, 'spin-imaging' of water in living systems has demonstrated the ability of NMR to obtain spatial discrimination[14]. The combination of high resolution ^{31}P NMR with some method of spatial selection could offer a unique opportunity for the study of metabolism in defined tissues and organs of an intact animal. However, because of the low sensitivity and difficulties with spectral resolution, many of the methods used in water imaging are not yet practical for ^{31}P spin-imaging of living systems. We describe here a simple method for detecting compounds in localised regions adjacent to the surface of the sample. We have used an unusual type of radiofrequency coil, which we call 'surface coil', to obtain the NMR signal. In this article we discuss the theory of the method, describe experiments on test phantoms, and show the application of the technique to the study of muscle and brain metabolism in living animals.

Theory and design of surface coils

The design of radiofrequency (r.f.) coils is best considered in terms of the theory of Hoult and Richards[15]. Let us consider a single r.f. coil that serves the role of both transmitter and receiver. Their theory shows that:

(1) The signal-to-noise ratio resulting from a 90° r.f. pulse applied to a small sample at point q is proportional to the value of $(B_1)_{xy}$ at that point. $(B_1)_{xy}$ is the component of the r.f. magnetic field in the xy plane (that is, in the plane perpendicular to the static field B_0) that is generated by unit current passing through the coil.

(2) The 90° pulse length for a sample at any point q is inversely proportional to the value of $(B_1)_{xy}$ at that point.

(3) The signal-to-noise ratio resulting from a single r.f. pulse of angle ϕ is proportional to $(B_1)_{xy} \sin \phi$. ϕ is equal to $\gamma (B_1)_{xy} i \tau$ where τ is the length of the pulse, γ is the magnetogyric ratio of the nucleus, and i is the current passing through the coil.

0028-0836/80/020167—04$01.00

Clearly the field distribution $(B_1)_{xy}$ produced by the coil is a critical factor in its performance. Conventional saddle-shaped and solenoidal coils are generally designed to produce a homogeneous B_1 field throughout the sample volume; this ensures that all regions of a uniform sample contribute equally to the signal. In contrast, we show that a different coil design enables us to observe signals from a selected region adjacent to the surface of the sample.

Consider a single-turn flat circular coil orientated as in Fig. 1. The magnetic field generated at any point q by unit current flowing in the coil is given by Smythe[16] and is

$$B_\rho = \frac{\mu}{2\pi}\frac{x}{\rho[(a+\rho)^2+x^2]^{1/2}}\left[-K+\frac{a^2+\rho^2+x^2}{(a-\rho)^2+x^2}E\right] \qquad (1)$$

$$B_x = \frac{\mu}{2\pi}\frac{1}{[(a+\rho)^2+x^2]^{1/2}}\left[K+\frac{a^2-\rho^2-x^2}{(a-\rho)^2+x^2}E\right] \qquad (2)$$

B_x and B_ρ are the axial (x) and radial (ρ) components of the field at point q, a is the coil radius, μ the permeability of the medium about the coil and K and E are complete elliptic integrals of the first and second kind.

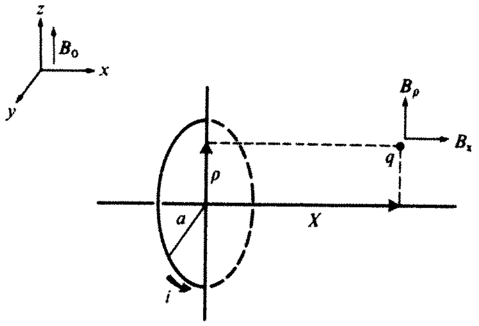

Fig. 1 Diagram illustrating the orientation of a single loop coil. Various parameters are B_0, the main magnetic field, a, the coil radius, i, the current flowing in the coil, and q, a point in space described by the coordinates (ρ, x). B_ρ and B_x are the B_1 field components at q resulting from current i. The angle θ formed by the vector ρ and B_0 is shown as 0 for clarity of presentation.

From Fig. 1, we see that the direction of B_x is always perpendicular to that of the static field B_0, while the perpendicular component of $B_\rho[(B_\rho)_{xy}]$ is given by

$$(B_\rho)_{xy} = B_\rho \sin\theta \qquad (3)$$

where θ is the angle between the directions of B_ρ and B_0 (see Fig. 1 where $\theta = 0$ for clarity of presentation). The magnetic field $(B_1)_{xy}$ generated at any point q therefore depends on θ and is given by

$$(\overline{B_1})_{xy} = \overline{B_x} + (\overline{B_\rho})_{xy} \qquad (4)$$

A plot of $(B_1)_{xy}$ as a function of ρ derived from equations (1)–(4) is given in Fig. 2 for the two extremes $\theta = 0$ and $\theta = \pi/2$.

Following from the relationships given above (points (1) to (3)), it is possible to map the $(B_1)_{xy}$ field of any r.f. coil. We have mapped $(B_1)_{xy}$ for a single-turn flat circular coil of radius 0.75 cm by placing a small sample (a disk of volume 0.01 ml containing 12 M phosphoric acid and 4 mM $NiCl_2$) at different positions q relative to the coil. The field $(B_1)_{xy}$ as determined from the variation in signal intensity is plotted in Fig. 2 and, as can be seen, shows good agreement with theory. Similar agreement was obtained from the variation in 90° pulse length, and from experiments with other surface coils. Note that the ^{31}P test sample was surrounded by an aqueous medium of 154 mM NaCl to approximate the electrical characteristics of animal tissue.

$(B_1)_{xy}$ is localised in a volume about the centre of the coil roughly defined by the coil radius (Fig. 2). It should therefore be possible to observe high resolution NMR signals from selected regions adjacent to the surface of the samples. Furthermore, we should stress that the region of sample contributing significant signal intensity will be spatially far more sharply defined than $(B_1)_{xy}$ due to the sine term in point (3) above.

Finally, as Hoult and Richards[15] have suggested, variations in phase of $(B_1)_{xy}$ should not affect this type of single coil experiment. This is because phase changes induced at transmission are mirrored at reception, and thus cancel. This conclusion was confirmed by our experiments.

Experiments with phantoms

To verify and more clearly illustrate the spatial resolution of surface coils, ^{31}P NMR experiments were performed on two different phantom samples. The first sample consisted of a two compartment rectangular box (10×2×1 cm) partitioned by a thin panel halfway along the length (5 cm) and filled with a solution of Na_2HPO_4 (100 mM) in one compartment and phosphocreatine (100 mM) in the other. ^{31}P NMR spectra were collected using a flat four-turn surface coil (mean radius 0.55 cm) placed outside the box at various positions along its length. The results are shown in Fig. 3. With the coil placed directly over the dividing partition, position 0.0, both compartments contribute equal signal intensity. When the centre of the coil is one radius from either side of the partition, only that compartment directly beneath the coil gives a signal. Thus sample selectivity (as a function of the radial, ρ, coordinate) is approximately confined to an area bounded by the coil circumference.

The second phantom consisted of a box (4×3×3 cm) filled with an aqueous solution of NaH_2PO_4 (20 mM) and NaCl (100 mM). The same coil was placed on the outside of the box (wall thickness 0.1 cm) and the ^{31}P spectrum obtained. A hollow

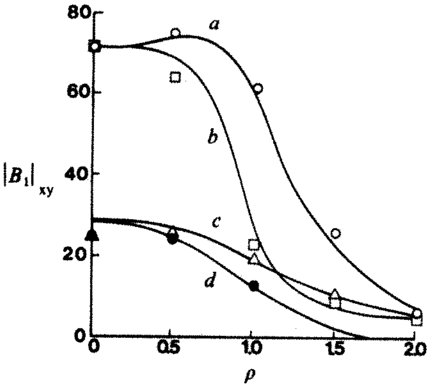

Fig. 2 The spatial dependence of $(B_1)_{xy}$ as a function of ρ, the radial coordinate. ρ is expressed in units of radius, a, while $(B_1)_{xy}$ is normalised to 100 at the centre of the coil, $(\rho, x) = (0, 0)$. The solid curves were derived from equations (1)–(4) while the symbols represent experimental data. Spatial parameters vary for each curve as follows: curve a, $\theta = \pi/2$ and $x \simeq 0.5a$; curve b, $\theta = 0$ and $x \simeq 0.5a$; curve c, $\theta = \pi/2$ and $x \simeq 1.1a$; curve d, $\theta = 0$ and $x \simeq 1.1a$.

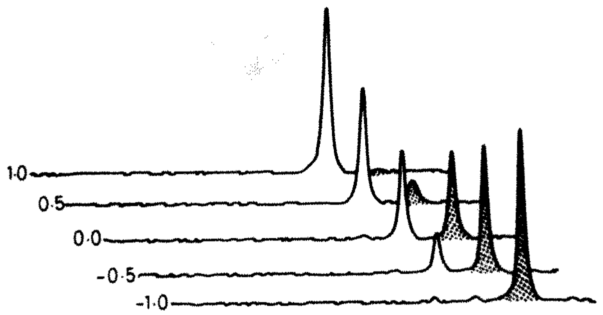

Fig. 3 Stacked plot demonstrating the radial, ρ, resolution of surface coils. The two ^{31}P resonances, each arising from a separate compartment in the phantom, are phosphocreatine (shaded) and inorganic phosphate (Na_2HPO_4) (non-shaded). The label associated with each spectrum is the distance (in units of coil radius, a) between the surface coil centre and the partition which separates the two compartments.

glass disk of radius 0.75 cm and thickness 0.5 cm filled with a solution of NaCl (154 mM) was then placed in the solution-filled box, immediately in front of the coil. On repeating the measurement, a sixfold reduction in signal intensity was observed. This results from the exclusion of 0.8 ml of the NaH_2PO_4 solution in front of the coil, illustrating the three-dimensional spatial selectivity of this type of NMR coil.

These experiments verify the theoretical predictions (Fig. 2) and the properties of these coils can be summarised as follows: (1) The high resolution NMR experiment can be performed with a surface coil external to the sample; (2) the spatial resolution is well defined and can be theoretically and experimentally determined; (3) this spatial resolution may be adjusted by appropriate choice of coil radius and pulse width; (4) the filling factors of surface coils compare favourably with those of conventional coils; and (5) noise generated by r.f. losses in conducting samples[17] arise only from those regions of the samples that contribute signal. These latter two points suggest that good signal-to-noise ratios can be expected with well-designed surface coils.

Measurements of metabolites in whole animals

The results and calculations presented above, together with studies on tissues and perfused organs provided the rationale for attempting to observe ^{31}P NMR spectra from muscle and brain of an intact rat.

Figure 4*a* shows the ^{31}P NMR spectrum obtained by placing the four-turn surface coil against the leg of an anaesthetised rat. The resonances arise from the three phosphates of ATP, phosphocreatine and inorganic phosphate (P_i), within the leg muscle. ^{31}P signals contributed by blood within the muscle tissue are negligible as fresh blood contains only a small amount of ATP and no phosphocreatine relative to 2,3-diphosphoglycerate[18]. (If 2,3-diphosphoglycerate were present in significant quantities, it would produce two signals with chemical shifts of about 5 and 6.5 p.p.m.)

To achieve conditions where peak areas are directly proportional to the amounts of tissue metabolites, a 12-s delay was used between sampling pulses. (This follows from the ^{31}P T_1 relaxation times for intracellular β-ATP (~1 s), phosphocreatine (~3 s) and inorganic phosphate (~3 s).) Thus the spectral accumulation of 128 scans required about 25 min. However, by reducing the delay between pulses, satisfactory spectra can be recorded in less than a minute. These can be used to follow changes in metabolites, to compare different metabolic states, or even to perform quantitative studies if the appropriate relaxation times or saturation factors are accurately determined[10].

A measure of the ATP concentration is obtained from the area of the signal at −16 p.p.m. (the β-phosphate peak of ATP). The resonance at −2.4 p.p.m. contains contributions from the γ-phosphate of ATP and the β-phosphate of mobile ADP. As the ratio of the areas of these two peaks ([ATP]/[ADP]+[ATP]) is one, within experimental error (0.94, $n = 5$, s.e.m. ± 0.05) clearly the concentration of mobile ADP is too low to be observed. The phosphocreatine to ATP ratio is 4.04 ± 0.18 ($n = 5$) which compares reasonably with recent freeze clamping values for rat skeletal muscle[19] but is considerably higher than other reported values[20]. Because phosphocreatine is rapidly degraded during ischaemia[1] we suggest that our *in vivo* ratio of phosphocreatine to ATP represents the best estimate so far for this parameter that reflects the energy status of the cell. The measurement of inorganic phosphate by freeze extraction procedures provides special difficulties, and it is significant that the NMR results give a phosphocreatine: P_i ratio of 14.6 ($n = 5$; s.e.m. ± 1.20). Assuming a phosphocreatine concentration of 23.1 μmol per g wet wt (ref. 19), the P_i concentration derived from NMR is 1.6 μmol per g wet wt, a value considerably lower than that derived from freeze clamping techniques[20]. This observation might explain why the activity of phosphorylase *b* in resting muscle is considerably less than that predicted by studies on the isolated enzyme combined with metabolic measurements by freeze extraction[21].

Following the observations of Moon and Richards[22] it has been well established that the position of the inorganic phosphate resonance provides a good measure of intracellular *p*H

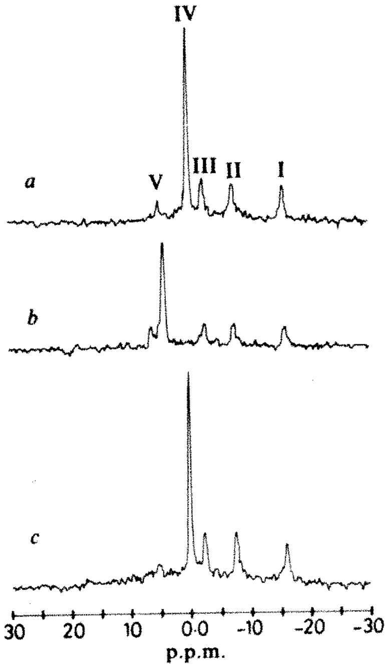

Fig. 4 ^{31}P NMR spectra of the leg muscle of an intact rat obtained with a surface coil. Each spectrum represents 128 scans over 25 min. A 15-Hz line-broadening exponential multiplication was used to enhance signal-to-noise. *a*, Non-ischaemic muscle below the knee joint; *b*, ischaemic muscle from the same area as in *a* after application of a tourniquet just above the knee; *c*, spectrum of muscle above the tourniquet. Chemical shift assignments for non-ischaemic rat leg muscle are β-phosphate of ATP (I), −16.10 ($n = 5$, s.e.m. ± 0.02), α-phosphate (II), −7.54 ($n = 5$, ±0.00), γ-phosphate of ATP (III), −2.47 ($n = 5$, ±0.02), phosphocreatine (IV), 0.00 by definition, and inorganic phosphate (V), 4.90 ($n = 5$, ±0.03). Chemical shifts are defined as positive in the high frequency direction and phosphocreatine is taken as an internal reference. Normally fed, pentabarbital anaesthetised male Wistar rats were used for all experiments. The rats were examined while in a vertical position. All experiments were done at 73.8 MHz on a spectrometer equipped with a wide-bore magnet.

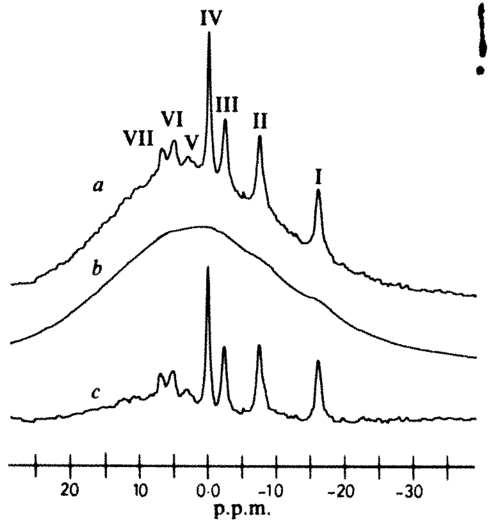

Fig. 5 ^{31}P NMR spectra of the brain of an intact rat obtained with a surface coil. Spectra *a–c* demonstrate the effects of the convolution difference technique in eliminating the broad ^{31}P component arising from bone. *a*, Original brain spectrum, 300 data accumulations over 60 min with a 15-Hz line broadening exponential multiplication; *b*, same as *a* except a 400-Hz line broadening exponential multiplication was used; *c*, difference spectrum of *a* minus *b*. Chemical shift assignments are β-phosphate of ATP (I), -16.20 ($n = 5$, ± 0.05), α-phosphate of ATP (II), -7.62 ($n = 5$, ± 0.02), γ-phosphate of ATP (III), -2.48 ($n = 5$, ± 0.02), phosphocreatine (IV) 0.00 by definition, phosphodiesters (V) 3.0 ($n = 3$, ± 0.1), inorganic phosphate and the 2-phosphate of 2,3-diphosphoglycerate (VI), 5.00 ($n = 5$, ± 0.007), and sugar phosphates and the 3-phosphate of 2,3-diphosphoglycerate (VII), 6.65 ($n = 5$, ± 0.06).

(refs 9, 10). The chemical shift of P_i within rat leg muscle is 4.90 ± 0.03 ($n = 5$), consistent with a *p*H of 7.1 ± 0.02 ($n = 5$).

In an experiment similar in philosophy to the two compartment phantom, the effect of localised ischaemia in the rat leg muscle was assessed (Fig. 4). A control muscle spectrum was obtained from just below the knee joint (Fig. 4*a*). Then a very tight tourniquet was placed around the leg just above the knee and a spectrum obtained from the same location as the initial control (Fig. 4*b*). The two spectra are significantly different. The ischaemic region of the muscle has no phosphocreatine, somewhat reduced amounts of ATP and a very large P_i concentration. In addition, the P_i chemical shift (4.31 p.p.m.) differs significantly from that in the control muscle (4.92 p.p.m.), indicating a more acidic *p*H of 6.7. (Similar results with excised tissue have been observed[1–3].) The small new peak at 6.30 p.p.m. may be attributable to the build-up of sugar phosphates or nucleotide monophosphate. Finally, with the tourniquet still in place, a spectrum was obtained from the leg muscle above the tourniquet (Fig. 4*c*). This spectrum is very similar to that of the first control, indicating healthy, non-ischaemic muscle. The localisation of ischaemic areas in diseased muscle is thus clearly possible.

One of the most difficult organs to study by biochemical and perfusion techniques is the brain. Because of the rapid oxidative metabolism and sensitivity to short periods of hypoxia or ischaemia of the brain, considerable effort has been spent in developing a variety of techniques such as 'freeze-blowing'[23], and cryo-NMR[8] to assess the *in vivo* energy status of this tissue.

By placing a surface coil on top of the rat's head, directly over the brain, we were able to obtain excellent ^{31}P spectra from the brain (Fig. 5). As there is no muscle tissue between the coil and the brain these experiments are selective for brain tissue and bone only. The very broad contribution from the bone can easily be eliminated by the convolution difference technique[24].

From the chemical shifts of the three ATP resonances in brain and muscle we can conclude that in both tissues the ATP is predominantly complexed to divalent cations which we assume to be Mg^{2+}.

The energy status of the live brain may be best compared with that of perfused or rapidly frozen tissue from the value of the phosphocreatine to ATP ratio. The value we derived from NMR (1.93 ± 0.12, $n = 5$) is higher than the best values obtained by rapid freezing[23]. In addition we estimate that the concentrations of both mobile ADP and P_i are much lower than those measured by destructive analytical techniques. In the brain spectrum the ratio of the resonances β-phosphate of ATP: γ-phosphate of ATP + β-phosphate of ADP is 1.07 ± 0.08 ($n = 5$) indicating that ADP is not detectable. The P_i signal is obscured by the 2-phosphate peak of 2,3-diphosphoglycerate present in blood. The 3-phosphate from the same compound is at 6.6 p.p.m. and indicates that the P_i concentration in the brain must be well below that of ATP, in contrast to values obtained from freeze extraction. These considerations lead to the conclusion that the phosphorylation state in brain tissue ($[ATP]/[ADP][HPO_4^{2-}]$) is at least an order of magnitude higher than the generally accepted value of $\sim 3{,}400\ M^{-1}$.

Conclusions

The use of surface coils to obtain high resolution NMR spectra from selected regions of large objects is clearly not limited to the systems described here. The design of the coil can be adapted to suit the sample. In animals, tissues other than muscle and brain (for example, fat tissue or cancerous growth) could be studied. Coupled with surgery, internal organs can easily be investigated[12].

An early low resolution application of flat coils has been for the measurement of blood flow[25]. Plant, fungal or non-living materials can also be examined in this way.

Influenza antigenic determinants are expressed from haemagglutinin genes cloned in *Escherichia coli*

J. S. Emtage, W. C. A. Tacon, G. H. Catlin, B. Jenkins, A. G. Porter & N. H. Carey

Searle Research Laboratories, Lane End Road, High Wycombe, Bucks, UK

A gene sequence for the fowl plague virus (FPV) haemagglutinin molecule has been inserted into a bacterial plasmid such that its transcription is under the control of a promoter derived from the tryptophan operon. Such plasmids direct the synthesis of a protein that reacts specifically with antisera to FPV haemagglutinin. Evidence is also presented that in some cases DNA inserted at the Hind*III site of pBR322 is expressed.*

INFLUENZA is still a major disease of man. It causes death primarily in the elderly, many of whom have chronic heart or vascular disease and other disorders. Severe infections of healthy individuals also occurs but in these cases morbidity, leading to incapacity to work, rather than mortality usually results. The morbidity figures however are of great economic importance. For example, the Hong Kong outbreak of 1968–70 resulted in 25 million lost working days in England[1], while in the US the effect of the Hong Kong variant of 1968–69 was costed at 3.8 billion dollars[2]. Thus, prevention of influenza epidemics and pandemics would be of value both economically and socially.

The main structure involved in immunity against influenza is the haemagglutinin (HA) surface glycoprotein[3,4]. The functional HA subunit, one of the spikes on the virus surface, is a triangular rod-shaped glycoprotein with a molecular weight of ~250,000 and is comprised of three HA monomers[5]. The HA monomers are synthesised as single polypeptide chains containing, in the case of FPV, an 18-amino acid precursor peptide at the N-terminus[6]. During maturation and virus assembly the pre-HA is further processed to HA1 and HA2 which remain linked by disulphide bridges[7,8].

Recent advances in genetic engineering and our knowledge of the structure and sequence of bacterial operons and control elements now allow the construction of new bacterial strains with the potential of synthesising large quantities of viral proteins (antigens) which may ultimately be useful as vaccines. In this article we describe the controlled production of haemagglutinin antigen from an HA gene cloned in *Escherichia coli*; this is the first step towards testing the feasibility of large scale antigen production by these means.

Experimental design

We have previously cloned at the *Hind*III site of pBR322 a DNA fragment containing the control region of the *E. coli* tryptophan operon, and coding for the ribosome binding site and first seven amino acids of *trpE*. From this, we have produced a series of vectors, pWT111, pWT121 and pWT131, capable of ensuring that any inserted DNA is read in the correct phase[9].

We recently cloned and sequenced the gene for the FPV haemagglutinin protein[6]. The gene was cloned using *Hind*III linkers and can therefore be transferred between vectors. From the nucleotide sequences of the FPV HA gene and the *Hind*III sites of the pWT series, it was clear that, if inserted at the *Hind*III site of pWT121 in the correct orientation, the HA gene would be translated by readthrough from the *trpE* fragment (Fig. 1*A*).

The protein resulting from initiation at the *trpE* AUG would be a hybrid consisting of the following fragments in order: (1) an N-terminus of 7 amino acids from anthranilate synthetase; (2) 6 amino acids specified by linker DNA; (3) 6 phenylalanine residues from the $(T)_{19}$ region of the FPV cloned DNA; (4) 7 amino acids from the normally non-translated 5′-portion of the HA gene; (5) 558 amino acids comprising the haemagglutinin protein and its prepeptide[6] and, finally; (6) 5 amino acids specified by *Hind*III linker at the C-terminus[9]. This is a total of 589 amino acids with a total MW of 69,000.

It was also clear that the HA gene should not be expressed from the initiator AUG of the *trpE* fragment in pWT111 or pWT131. Recognition of the ribosome binding site and initiator AUG of the HA was not anticipated. Similarly, we did not expect expression of the HA gene inserted at the *Hind*III site of pBR322 in either orientation.

Construction of expression plasmids

pWT121 was restricted with *Hind*III, treated with alkaline phosphatase, ligated to the purified HA gene and the mixture used to transform *E. coli* K12 HB101. A total of 47 ampicillin resistant transformants was obtained (pWT121 in the absence of the HA gene produced 13 colonies). Of these 47 colonies, 19 were tetracycline sensitive (Tc^S) and the remainder tetracycline resistant (Tc^R). We selected 12 colonies ($3Tc^S$ and 9 Tc^R) for further characterisation. Analysis of plasmid DNA by gel electrophoresis after *Hind*III restriction showed that 5 of the 9 Tc^R colonies contained plasmids with a DNA insert. The other four contained the parent plasmid.

The orientation of the inserted DNA was determined by restriction enzyme analysis of the plasmids. We denote the two orientations as either R or L and define R and L orientation in terms of the direction of transcription required for HA

Fig. 1 *A*, Predicted nucleotide sequences around the *Hind*III sites of pWT111, pWT121 and the FPV-HA gene. Arrows indicate the position of the *Hind*III sites and, for clarity, only the sequence of the coding strand is shown. The protein sequence of the N-terminus of anthranilate synthetase has previously been reported by Lee *et al*[10]. The numbering system is bidirectional beginning with the 5′-nucleotide of the gene 4 complementary RNA. *B*, Potential base pairing between the 3′oligonucleotide of *E. coli* 16S RNA[11] and the pre-AUG region of the haemagglutinin mRNA.

0028–0836/80/020171—04$01.00

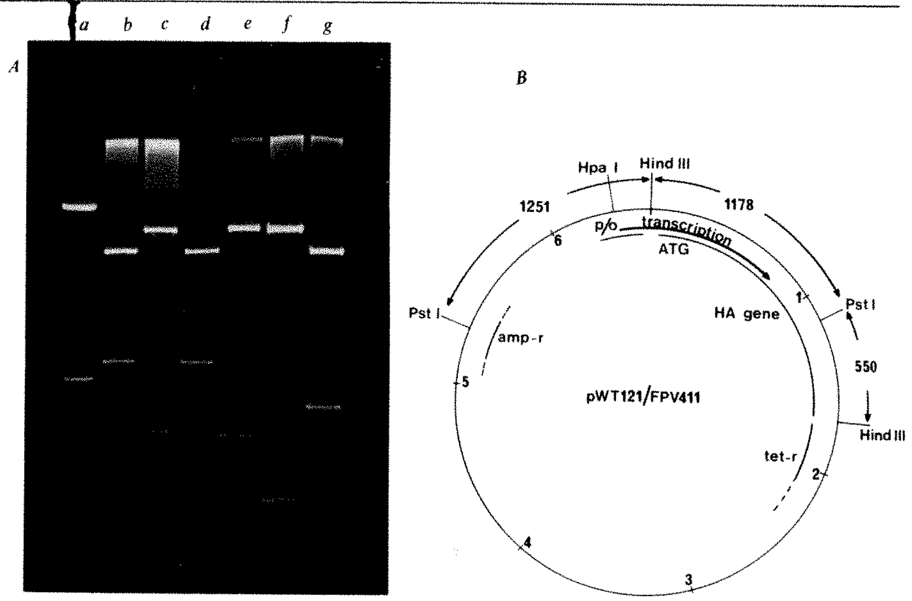

Fig. 2 *A*, Orientation of the FPV gene in pWT111, pWT121 and pBR322. pBR322, pWT111 or pWT121 (10 μg) was limit digested with *Hin*dIII. The resulting 5′-terminal phosphates of the vectors were removed by treatment with 20 μg bacterial alkaline phosphatase for 30 min at 37 °C in a 25 μl incubation containing 20 mM Tris-HCl *p*H 7.5 and 0.1% SDS. After phenol extraction and ethanol precipitation 0.2 μg of each DNA was ligated to ~40 ng FPV-HA gene in a 20 μl incubation containing 50 mM Tris-HCl *p*H 7.5, 10 mM $MgCl_2$, 20 mM dithiothreitol, 1 mM ATP and 0.02 units T4 DNA ligase (New England Biolabs). After overnight incubation at 15 °C the mixtures were diluted to 100 μl with TCM (10 mM Tris-HCl *p*H 7.5, 10 mM $CaCl_2$, 10 mM $MgCl_2$) and used to transfect 200 μl $CaCl_2$-treated *E. coli* K12 HB101 by a previously described procedure[12]. Transformants present after growth for 16 h at 37 °C on L-agar[13], plus 100 μg ml^{-1} carbenicillin (Pyopen) were tested for tetracycline resistance by picking onto agar plates containing M9 salts, glucose and casamino acids[13] plus carbenicillin and tetracycline (10 μg ml^{-1}). For plasmid isolation colonies were picked and 100-ml cultures grown in M9 salts, glucose, casamino acids medium supplemented with carbenicillin. At an A_{600} of ~0.6, choramphenicol was added to a final concentration of 150 μg ml^{-1} and incubation continued for 16 h at 37 °C. Cells were killed by the addition of diethylpyrocarbonate[14] to 0.4%, collected by centrifugation, washed with TE buffer (10 mM Tris-HCl *p*H 7.5, 1 mM EDTA) and suspended in 1.5 ml of iced 25% sucrose in 50 mM Tris-HCl *p*H 8. Cells were lysed by the addition of 0.5 ml lysozyme (10 mg ml^{-1}, 0.5 ml EDTA (0.5 M, *p*H 8) and 2.5 ml iced Triton solution (0.1% Triton X-100, 50 mM Tris-HCl *p*H 8, 50 mM EDTA) at 5-min intervals. The resulting lysates were cleared by spinning at 15,000*g* for 20 min, extracted with phenol and then chloroform and finally precipitated by the addition of 0.1 vol 3M NaAc and 0.54 vol isopropanol. After 30 min at −20 °C the DNA was pelleted, washed with 70% ethanol, dried and dissolved in TE. *Pst*I digests were carried out on 0.1 μg DNA in conditions recommended by the vendor (New England Biolabs) with the modification that RNase (50 μg ml^{-1}) was included in the incubation. Digests were fractionated on a 1.4% agarose slab gel[15] and bands visualised under UV light after staining with ethidium bromide. Lane *a* contains PM-2 DNA digested with *Hin*dIII. Bands seen are 5,400, 2,350 and 1,050 base pairs. The other lanes contain *Pst*I digests of the following plasmids: *b*, pWT121/FPV 411(R); *c*, pWT121/FPV 412(L); *d*, pWT111/FPV 502(R); *e*, pWT111/FPV 503(L); *f*, pBR322/FPV 604(L); *g*, pBR322/FPV 605(R). *B*, Structure of pWT121/FPV 411(R). pWT121 contains a single *Hin*dIII site downstream from the *trp* promoter[9]. The plasmid shown contains the FPV-HA gene cloned at the *Hin*dIII site in the R orientation. The distances between the *Pst*I and *Hin*dIII sites are shown as well as the direction of transcription from the *trp* promoter and the position of the initiator ATG. A full description of the construction of the pWT plasmid series has been published elsewhere[9]. Briefly, the 497-base pair *Hin*fI fragment containing the *trp* promoter/operator region as well as the nucleotides specifying the leader sequence and first seven amino acids to *trpE* (ref. 10) was isolated and cloned, using *Hin*dIII linkers, into the *Hin*dIII site of pBR322. From this a plasmid, pWT101, was isolated containing the *trp* promoter in the R orientation. In pWT101 tetracycline resistance is controlled from the *trp* promoter. Elimination of the *Hin*dIII site upstream of the *trp* promoter produced the vector pWT111 and phase changing at the *Hin*dIII site of pWT111 using DNA polymerase I and *Hin*dIII linkers produced pWT121 and pWT131.

production. That is, a gene in the R orientation required rightward (clockwise) transcription for expression; in the pWT plasmid series this is the orientation for expression from the *trp* promoter. For clarity we have included the letter (R) or (L) after the plasmid number to indicate its orientation. pWT121 contains a single *Pst*I site, in the ampicillin gene[16], 1,251 base pairs from the *Hin*dIII site and the FPV HA gene contains a *Pst*I site 1,178 base pairs from the 5′ end of the coding strand[6]. Thus *Pst*I digests of the recombinant plasmids should indicate which are correctly orientated with respect to the *trp* promoter. Representatives of the two FPV-gene containing groups are shown in Fig. 2*A* (*b* and *c*). The Tc^S plasmids gave rise to a band of 1,800 base pairs on *Pst*I digestion while the Tc^R plasmids produced one of 2,450 base pairs. These are consistent with the fragments expected from the plasmid shown in Fig. 2*B* and indicate that all the Tc^S plasmids contained inserts in the L orientation while the Tc^R plasmids contained inserts in the R orientation.

In a similar way we re-cloned the HA gene into the *Hin*dIII site of pWT111 and pBR322. Again the pWT111/FPV plasmids could be divided into Tc^R and Tc^S groups and *Pst*I restrictions (Fig. 2*A*, *d* and *e*) of representatives of these groups indicated that the HA gene was in the R orientation in the Tc^R group and in the L orientation in the Tc^S group. The pBR322/FPV plasmids however were all Tc^S but still contained L and R orientated genes as shown in Fig. 2*A* (*f* and *g*).

The correct phasing of the HA gene in pWT121/FPV 411(R) with the *trpE* AUG was confirmed by nucleotide sequencing. The HA gene contains an *Eco*RII restriction site at positions 36–40 (ref. 6). This site, however, is methylated and although not cleaved by *Eco*RII, it is cleaved by the *Eco*RII isoschizomer *Bst*N1. Therefore we digested pWT121/FPV 411(R) with *Bst*N1, labelled the 5′ ends with ^{32}P, recut the DNA with *Hpa*I and isolated the fragment containing the initiation region. The nucleotide sequence of this fragment was complementary to the sequence predicted in Fig. 1*A*, except for nucleotide −36 which was an A instead of a G. This was also the case for the corresponding position in pWT111. In both plasmids this position corresponds to the 3′-terminal nucleotide of the *Hin*dIII linker. The reason for the change is not clear; it might be due to random mutation or, more likely, to micro-heterogeneity or incomplete deblocking after chemical synthesis at the 3′ ends of the *Hin*dIII linker. In either event the effect in the mRNA strand is to have a serine codon (UCG) instead of a proline codon (CCG) but does not change the phase with respect to the *trpE* AUG.

Gene expression

E. coli colonies containing representatives of the plasmids described above were screened for FPV-HA antigen using a solid-phase immunological method[17]. Briefly, small cultures of individual colonies were grown, collected and lysed using lysozyme and Triton X-100. Any HA sequences present were

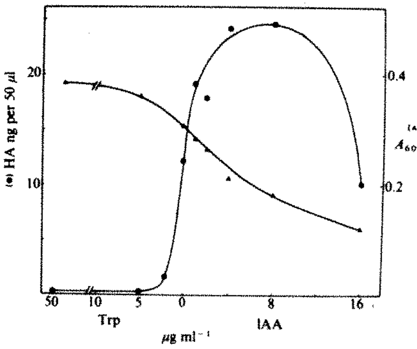

Fig. 3 Control of HA production. Overnight cultures of *E. coli* K12 HB 101 containing pWT121/FPV 411(R) were grown in M9 salts, glucose, casamino acids medium supplemented with carbenicillin (100 μg ml^{-1}). Aliquots of 100 μl were inoculated into 5 ml of the above medium containing either tryptophan or IAA as indicated. Cultures were grown for 2 h at 37 °C, the A_{600} determined and cells collected, lysed and assayed for HA content as described in Table 1.

Table 1 Radioimmunoassay of FPV-HA in lysates of bacteria containing influenza genes

Plasmid	Orientation of gene	Phenotype	HA content (ng per 50 μl)
pWT121/FPV 411	R	Tc^R	20.3
pWT121/FPV 412	L	Tc^S	5.0
pWT111/FPV 502	R	Tc^R	4.1
pWT111/FPV 503	L	Tc^S	2.1
pBR322/FPV 604	L	Tc^S	3.6
pBR322/FPV 605	R	Tc^S	0
pWT121	—	Tc^R	0
pBR322	—	Tc^R	0

Liquid cultures (5 ml) of individual colonies were grown in M9 medium. Cells were collected by centrifugation, and lysed, in a final volume of 1 ml, as described in Fig. 2*A*. This lysate was used for antigen assay without further treatment. HA-antigen assays were performed in polystyrene culture tubes (Nunc no. 1410) using an antibody sandwich technique[17]. Rabbit anti-FPV HA was purified by ammonium sulphate precipitation and DEAE-cellulose chromatography[18] before use and labelled with ^{125}I as described elsewhere[19]. Tubes were coated with 50 μl of 0.2M $NaHCO_3$*p*H 9 containing 60 μg ml^{-1} purified, unlabelled IgG for 10 min at room temperature, washed with 3 × 1-ml aliquots of wash buffer (phosphate-buffered saline containing 0.1% bovine serum albumin, 0.1% NP-40 and 0.5% normal goat serum) and then incubated at room temperature either with known amounts (1–20 ng) of Sarkosyl-disrupted FPV or with the bacterial lysates. After 2 h, the tubes were washed with 4 × 1-ml aliquots of wash buffer and finally incubated at 4°C for 16 h with 50 μl wash buffer containing 200,000 c.p.m. ^{125}I-anti-HA. Tubes were again washed and counted in a Packard γ-counter. Antigen present was quantitated from standard curves relating the radioactivity bound to the amount of FPV present.

bound to a polystyrene tube coated with FPV-HA specific IgG. Bound antigen was then detected by incubating with high specific activity ^{125}I-anti FPV-HA. As indicated in Table 1, immune reactivity was detected from all colonies containing an FPV-HA gene inserted into the pWT plasmids and from pBR322 containing the HA gene in the L orientation. Neither of the parent plasmids nor pBR322 containing the HA gene in the R orientation produced any immune reacting material. Further, the positive reactions were abolished if the tubes were coated either with normal rabbit IgG or with anti A/Victoria—HA IgG instead of specific anti-FPV-HA IgG.

It was interesting to find expression of HA antigen from one orientation of pBR322/FPV. The *Hin*dIII site of pBR322 lies in the promoter region of the tetracycline gene and it is known that cloning at the *Hin*dIII site destroys this rightward transcribing promoter[20] unless the cloned DNA has its own promoter transcribing into the tetracycline gene(s)[21]. We therefore propose that a previously unknown promoter which transcribes in the leftward direction exists on the tetracycline gene side of the *Hin*dIII site of pBR322. It is necessary to postulate the existence of this promoter to explain the expression of the HA gene in pBR322/FPV 604(L), pWT121/FPV 412(L) and pWT111/FPV 503(L). The possibility that there is a pseudopromoter sequence in the HA gene itself, for example the (T_{19}):(A_{19}) sequence, is ruled out as the plasmid pBR322/FPV 605(R) does not express its HA gene (Table 1).

This postulated promoter would explain the transcription of the HA gene in the L-orientated plasmids. How is translation explained? Inspection of the nucleotide sequence around the tetracycline–HA gene junction of pBR322/FPV 604(L) reveals nonsense triplets in all three translation phases[22]. Thus the bacterial translational system is probably recognising a nucleotide sequence on the HA mRNA itself and initiating protein synthesis at the AUG of the pre-peptide. Comparison of the sequence of the untranslated region of the HA gene with that of the 3′ end of prokaryotic 16S ribosomal RNA[11] reveals surprising complementarity (Fig. 1*B*). Consistent with this interpretation is the expression of HA antigen in pWT111/FPV 502(R). In this case the HA gene is in the wrong phase to be translated from the *trpE* AUG; protein synthesis initiating at the *trpE* AUG is terminated by the now in phase UGA triplet at position 23–25 in the HA gene. Thus we conclude that initiation is from the natural HA AUG at position 22–24 (Fig. 1*A*). Assuming equal transcription from the *trp* promoter in pWT121/FPV 411(R) and pWT111/FPV 502(R) and that the products have equal antigenic properties, then from the data of Table 1 we conclude that the eukaryotic ribosome binding site is recognised with an efficiency of 20% compared to the prokaryotic site.

The fivefold difference in HA expression between pWT121/FPV 411(R) and pWT111/FPV 502(R) could be due to differences in the plasmid complement of the respective cells. To exclude this possibility the relative copy numbers of the above plasmids were determined from agarose gels of lysed whole cells[9] and found to be the same (data not shown).

Hitherto the *Hin*dIII and *Eco*RI sites of pBR322 have been assumed to be non-expression sites because of their respective situations in and upstream of the tetracycline promoter[20,21]. This has been thought to be of value in assessing the containment categorisation when considering the safety of experiments in genetic engineering[23]. In view of the above findings it is clear that the validity of these assumptions should be reassessed. It seems likely that a potential ribosome binding site on the inserted gene will be of some importance.

Table 2 Control of HA expresion from the tryptophan promoter/operator region

Plasmid	Addition	HA* (ng per 50 μl)
pWT121/FPV 411(R)	Tryptophan	0.9
	IAA	59.1
pWT121/FPV 412(L)	Tryptophan	9.6
	IAA	4.9

Cultures (5 ml) of pWT121/FPV 411(R) and pWT121/FPV 412(L) were grown for 3 h at 37 °C in M9 salts, glucose, casamino acids medium supplemented with carbenicillin (100 μg ml^{-1}) and either IAA (20 μg ml^{-1}) or tryptophan (100 μg ml^{-1}). Cells were collected, lysed and assayed for HA content as described in Table 1.

* Results normalised to same A_{600}.

Control of gene expression

In vivo the tryptophan operon is controlled by the level of tryptophan[24] and control is best obtained in culture by using tryptophan as repressor or β-indole acrylic acid (IAA) as inducer. The latter is a competitive inhibitor that prevents tryptophan binding and thereby effectively inactivates the repressor[25].

We selected a representative colony from each of the two expressing groups (in pWT121) to examine HA synthesis in the above conditions. Our initial observation was that pWT121/FPV 411(R) grew very slowly in the presence of 20 μg ml^{-1} IAA; there was a threefold difference compared to growth in the presence of tryptophan. pWT121/FPV 412(L) grew equally well in both sets of conditions. The results of radioimmunoassay of these cultures are shown in Table 2. Because of the differences in growth rate, the values are all normalised to the A_{600} of the culture containing pWT121/FPV 411(R) plus tryptophan. In pWT121/FPV 411(R), HA production is stimulated 65-fold when the *trp* operon is derepressed. In contrast, IAA decreased HA synthesis in pWT121/FPV 412(L). Thus increased transcription from the *trp* promoter is competing with transcription from the presumed promoter near or around the tetracycline gene and reducing expression in the leftward direction.

The effects of repression and induction on HA synthesis are also seen in Fig. 3. As little as 5 μg ml^{-1} tryptophan was sufficient for maximal repression. On the other hand, because of its effect on growth, the induction characteristics of IAA were more complex. Maximal induction occurred at IAA concentrations of 4–8 μg ml^{-1} and HA synthesis was stimulated 120-fold over the repressed level.

Finally, we examined the immunoprecipitable products in cells containing various plasmids after induction or repression of *trp* transcription. At 3 h after addition of either IAA or tryptophan to cultures of such cells, aliquots were pulse-labelled with ^{35}S-methionine and the immunoprecipitable proteins separated by SDS-polyacrylamide gel electrophoresis. No immunoprecipitable proteins were present in induced cells containing pWT121 or in repressed cells containing pWT121/FPV 411(R) (Fig. 4*a* and *b*, respectively). However, induced cells containing pWT121/FPV 411(R) or pWT111/FPV 502(R) and repressed cells containing

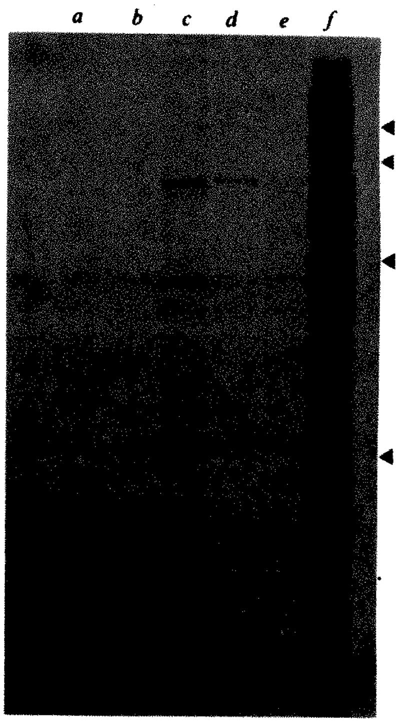

Fig. 4 Immunoprecipitation of the haemagglutinin-like protein. Cultures of *E. coli* K12 HB101 containing the plasmids pWT121, pWT121/FPV 411(R), pWT121/FPV 412(L) and pWT111/FPV 502(R) were grown in M9 salts, glucose, casamino acids medium containing carbenicillin (100 μg ml^{-1}) and either IAA (10 μg ml^{-1}) or tryptophan (40 μg ml^{-1}). After a 3-h period, 5-ml samples were removed and pulse-labelled for 10 min at 37 °C with 50 μCi of ^{35}S-methionine. The labelling was terminated by the addition of 20 ml cold M9 medium, the cells pelleted by centrifugation at 12,000*g* for 10 min at 4 °C and lysed, in a final volume of 1 ml, as described in Fig. 2*A*. Immunoprecipitations were performed as follows: to 400 μl *E. coli.* extract was added 2 μl 10% Nonidet P-40 (NP–40), 4 μl (2μg) normal rabbit IgG and the mixture incubated for 60 min at 20 °C. An aliquot of 10 μl of a 10% suspension of killed *Staphylococcus aureus*[31] (Cowan 1 strain) was then added and incubation continued for a further 15 min. The resulting immunoprecipitate was pelleted and discarded. To the supernatant was added 2 μg rabbit anti FPV-HA and, after 60 min at 20 °C, 10 μl of *S. aureus.* This immunoprecipitate was pelleted 15 min later and washed twice with a solution containing 0.15 M NaCl, 5 mM EDTA, 50 mM Tris-HCl *p*H 7.4 and 0.05% NP-40. Radioactive proteins were eluted from the complex with 30 μl SDS buffer, heated 90 °C for 2 min and electrophoresed on a 12.5% polyacrylamide-SDS gel[32] which was then dried and autoradiographed. The figure shows the immunoprecipitable proteins from cells containing the following plasmids: *a*, pWT121 + IAA; *b*, pWT121/FPV 411(R) + *trp*; *c*, pWT121/FPV 411(R) + IAA; *d*, pWT111/FPV 502(R) + IAA; *e*, pWT121/FPV 412(L) + *trp*; *f* contains an extract from induced cells containing pWT121/FPV 411(R). The positions of conalbumin (MW 76,000), bovine serum albumin (69,000), ovalbumin (43,000) and carbonic anhydrase (30,000) are indicated by the arrows.

pWT121/FPV 412(L) all produced a band of MW 61,000 (Fig. 4*c*, *d* and *e* respectively). Our experimental design predicted that the HA-like protein synthesised from pWT121/FPV 411(R) would have a MW of 69,168 and that the products from pWT121/FPV 502(R) and pWT121/FPV 412(R) would be 26 amino acids smaller at the N-terminus. As the three products are in fact the same size, it seems probable that the primary gene product has been processed and a portion of the polypeptide removed. The same results were obtained when the products of these plasmids were examined in minicells (unpublished results). Clearly the mechanism of the processing and the possible involvement of the pre-HA sequence need further investigation.

Conclusions

We have demonstrated the feasibility of producing controlled amounts of influenza antigenic determinants by genetic engineering. Obviously further analysis is necessary to characterise the protein product and a number of questions remain unanswered. First, for example, initiation of protein synthesis from the prokaryotic-like ribosome binding site on the HA will result in a polypeptide having a eukaryotic leader sequence. This sequence is thought to function in the transmembrane movement of the HA *in vivo*[26]; we may question whether this sequence is recognised by the regulatory systems for export in bacteria. Second, what effect do the $(T_{19}):(A_{19})$ region, resulting from the oligo(dT) primer and the poly(A)tail of the vRNA and situated between the AUG of *trpE* and the HA sequence, or the $(Phe)_6$ oligopeptide resulting from its translation, have on transcription and translation respectively? Homopolymeric nucleotide regions such as this are one of the signals implicated in transcription termination[27]; thus the $(T_{19}):(A_{19})$ region may have a polar effect on HA production. Similarly, the $(Phe)_6$ region may result in depletion of charged $tRNA_{Phe}$ and slow ribosome movement along the mRNA. Clearly examination of HA production by plasmids where this region has been removed is essential.

The absolute quantity of HA-like protein produced may also be estimated. The estimates based on immunological detection cannot be precise and are probably minimum values since if there are differences from the natural antigen it seems likely that the bacterial product would have fewer antigenic determinants or lower affinity for the antiserum. Based on our maximum yield of 60 ng per 50 μl bacterial lysate (Table 2) and a protein concentration of 160 μg ml^{-1} for the same lysate we arrive at a figure of 0.75% of total protein. By comparison, the quantities of induced proteins can be determined by densitometry from autoradiographs of gels containing proteins from induced and repressed cells. This shows that the 61,000 MW protein is 2–3% of total protein synthesis (unpublished results). Neither of these values was as high as expected. Hallewell and Emtage[28] have recently cloned an *E. coli HindIII* fragment containing the *trp* promoter and the complete *trpE* gene in pBR322; in induced conditions this plasmid was capable of specifying up to 30% of total protein as anthranilate synthetase[28]. Our values however are similar to those reported for the synthesis of ovalbumin-like proteins under the control of the *lac* promoter[29,30]; that is, the level of expression of the eukaryotic genes is only about 10% of the expected. Whether this is due to limiting amounts of some tRNA species as proposed by Fraser and Bruce[30] or to the type of transcription termination discussed above remains to be seen.

We thank Drs J. Oxford and M. Gethin for gifts of rabbit anti-FPV HA and *Staphylococcus aureus* respectively and Dr A. Hale for providing research facilities. Cloning and expression experiments were performed in a CIII laboratory as recommended by GMAG.

A search for neutral hydrogen absorption in the double quasar 0957+561

C. L. Bennett, C. R. Lawrence & B. F. Burke

Department of Physics and Research Laboratory of Electronics,
Massachusetts Institute of Technology,
Cambridge, Massachusetts 02139

We report here the results of a search for neutral hydrogen absorption in the spectrum of 0957+561. This source consists of two quasars with similar optical spectra and Mg II absorption redshifts, and an extended region containing most of the radio flux. We place limits on the optical depth of intervening hydrogen of 0.02 and 0.23, depending on whether such hydrogen covers all of the source or only the compact components.

The quasars 0957+561 A, B were discovered by Porcas *et al.*[1] as two blue objects of nearly equal magnitude, separated by 6 arc s. Walsh *et al.*[2] have suggested that these two objects, having the same redshifts and essentially identical optical spectra, may be one source split into two images by a gravitational lens. High resolution maps at 6 cm by Roberts *et al.*[3] and Pooley *et al.*[4] do not disprove this model, but an equally likely and possibly simpler interpretation is that the source is a true double quasar, with one component presently ejecting relativistic plasma[3]. Spectroscopic observations by Weymann *et al.*[5] on the multiple mirror telescope give heliocentric vacuum Mg II absorption redshifts of 1.3911 for A and 1.3912 for B.

The radio absorption line observations reported here were conducted on the 300-ft telescope of the National Radio Astronomy Observatory in Green Bank, West Virginia, during a two week period in June 1979. The 515–740 MHz dual channel receiver, with a system temperature of about 130 K, was used to search the redshift range 1.388–1.394. Spectra were processed by the Mark III autocorrelator running in a parallel mode, with 192 channels devoted to each of the two independent receivers. A bandwidth of 2.5 MHz was used, yielding a channel spacing of ~3.5 km s^{-1}. The system was operated in the total power mode with off-source scans taken before and after on-source scans. The total on-source integration time was ~2h for each receiver, and the two receivers were averaged together in the data reduction. The resulting spectrum is shown in Fig. 1, and shows no evidence for neutral hydrogen absorption lines deeper than 0.02 K. The spectrometer system was checked by observing the H II region W43. The 222α hydrogen recombination line at 595.01 MHz was seen at the expected intensity.

Continuum antenna temperature measurements were made at 594 MHz with the same receiver; however, there is a confusing source, 4C+55.19, about 16 arc min south-east of the quasars (2/3 power point in the beam), of unknown 594 MHz flux. This source is clearly seen at the extreme edge of a full field VLA map of 0957±561 at 20 cm (Roberts, personal communication), but it is so far off-centre that the flux is unreliable. We estimate that the 594 MHz flux of 0957+561 is about 1 Jy, based on fluxes at 20 cm (Roberts, personal communication) and at 73 cm (Pooley *et al.*[4]). The corresponding 300 ft antenna temperature is ~0.9 K. The flux at 6 cm was measured with the 6–25 receiver, which has a system temperature of about 80 K, and found to be 230±20 mJy. Both measurements were made in July 1979.

The 6 cm VLA map of Roberts *et al.*[3] has an angular resolution of 0.8 arc s, and shows a pair of unresolved sources coincident with the optical quasars A and B (A being northernmost). In addition, there is a double, extended source 2–5 arc s north-east of A, and a probable extended source 5 arc s south-west of A, these sources being designated C, D, and E respectively by Roberts *et al.*[3] If the entire complex is covered by the absorber, the 0.02 K absorption limit and the 0.9 K estimated antenna temperature place an upper limit on the optical depth of $\tau \leqslant 0.02$. As we do not know where the optical lines are formed, however, this assumption may not be valid. A more conservative assumption is that only the compact sources A and B, which show almost identical Mg I, Mg II, and Fe II optical absorption lines, are covered. Of the total VLA flux of 220 mJy, source A contributed 36 mJy, and source B 30 mJy. Pooley *et al.*[4] report a 408 MHz flux of 120 mJy for A, and an upper limit of 50 mJy for B. Interpolating the fluxes between these two frequencies, we estimate that the combined 594 MHz flux of A and B lies between 100 and 150 mJy. In this case, our limit on the optical depth would be $\tau \leqslant 0.23$.

Both optical and radio absorption lines have been detected in the spectra of other compact sources. The Mg II and Fe II optical lines in the BL Lac object AO0235+164 and the quasar 1331+170 are the most similar to those in 0957+561; optical and radio results for these three are summarised in Table 1.

The equivalent widths of the optical lines in 0957+561 are intermediate between those of AO0235+164 and 1331–170. If the absorbing material covers only A and B, the resulting optical depth limit of $\tau \leqslant 0.23$ is consistent with the known optical depths of the H I absorption lines in the other two sources. Alternatively, if the absorber covers some or all of C, D, and E, the peak optical depth of 0.02 may imply a higher spin temperature or a lower density for the hydrogen in this absorber than for that in the other two absorption systems.

To place a limit on $n_{\rm H}$, the column density of hydrogen, we assume a rest frame line width of 10 km s^{-1}. With spin temperature $T_{\rm s}$, the limits are $(n_{\rm H}/T_{\rm s}) < 4 \times 10^{18}$ H cm^{-2} K^{-1} for $\tau < 0.23$, and $n_{\rm H}/T_{\rm s} < 4 \times 10^{17}$ H cm^{-2} K^{-1} for $\tau < 0.02$.

The optical lines are unresolved and highly saturated, so that only approximate information about column densities of Mg II can be extracted. From the equivalent widths of Weymann *et al.*[6] the doublet ratio of the Mg II lines is 0.92 for source A and 1.04

for B. Since the doublet ratio decreases from 2 to 1 as the ion density increases, we interpret the A value of 0.92 as a reflection of measurement uncertainties, and assign error limits to the B ratio of $1.04^{+0.08}_{-0.04}$. The resulting upper limit of 1.12 in the doublet ratio of Mg II corresponds to a lower limit on the column density of $n_{\mathrm{MgII}} > 10^{15}\ \mathrm{cm}^{-2}$. For $\tau < 0.23$ and $T_s > 10$ K this limit is consistent with cosmic abundances; for $\tau < 0.02$ spin temperature would have to be >100 K. These limits are, of course, strongly dependent on the equivalent widths of the unresolved optical absorption lines.

Emission feature λ 3,470 of VV Puppis may be a cyclotron line

I. G. Mitrofanov

A. F. Ioffe Physics and Technology Institute, USSR Academy of Sciences, Leningrad 194021, USSR

The possibility that the unidentified emission feature λ 3,470 in the spectrum of VV Puppis is a cyclotron line is discussed and a theory to explain such an origin is presented.

VV Puppis displays a large linear and circular polarisation $P_{\mathrm{max}} \simeq q_{\mathrm{max}} \simeq 16\%$ (ref. 1) showing it to be an object of the AM Herculis type. These objects (AM Her, AN Ursae Majoris, VV Pup and 2A0311 − 227) are close binary systems containing an outflowing non-degenerate star and an accreting degenerate dwarf. Stars of the AM Her group have no erruptions and probably belong to the nova-like class. The polarisation of VV Pup light changes regularly with an orbital period of ~100 min. During ~60% of this period VV Pup usually increases its luminosity. Its magnitude varies from $m_{\mathrm{min}} = 14.4$–18 to $m_{\mathrm{min}} - \Delta m$ mag where $\Delta m = 0$–2.5. There seems to be no clear correlation between the m_{min} and Δm variations. The maximum positive circular polarisation q_{max} is observed in the phases of the orbital period when VV Pup is photometrically bright. In the phases of minimum light the circular polarisation is weaker and negative. The magnitude of q_{max} appears to change from one observation to another.

Although the VV Pup spectrum usually has strong H and He II emission lines, Angel *et al.*[2] have observed that this star sometimes has an unusual state of steady low luminosity with no strong H and He II emission. According to a more detailed description of these observations[3], in March and April 1977 VV Pup was in two different states. In March the magnitude in the minimum phases was small $m_{\mathrm{min}} \simeq 17.7$, brightening was large $\Delta m \simeq 2.5$ and the H and He II emission lines were strong. The average Hβ flux was about 1% of the continuum 3,500–6,000 Å flux. In April the minimum light was approximately the same, but brightening was small $\Delta m \leq 0.5$ and the spectra has no strong H, He or some other elements emission (Hβ flux did not exceed 0.02% of the 3,500–6,000 Å continuum). Nevertheless, a strong unidentified emission line near 3,470 Å was statistically significant[3] in both spectra obtained by a single-channel prism scanner of the Steward 2.3-m telescope (Fig. 1) and a Kitt Peak 4-m intensified image-dissector scanner.

The unidentified line cannot be an atomic line of some element, because other lines of such an element would also be observed. The feature has been observed using different equipment, so the coincidence of any systematic errors or 'glitches' seems unlikely. The feature corresponded to energy flux of about 3% of the 3,500–6,000 Å continuum, that is, it was very strong. When VV Pup was in the active state (March 1977), the emission feature λ3,470 was much smaller[3].

One possibility is that the strong emission feature λ3,470 is a cyclotron line. The magnetic field B corresponding to the wavelength of this line is equal to 3.1×10^8 G. The accuracy of this determination depends on the spectral width of the feature, the estimated error is $\Delta B = (\Delta\lambda/\lambda) \times B \approx 10^7$ G.

This magnitic field is likely to belong to the degenerate component of VV Pup. The presence of a magnetised degenerate dwarf in the AM Her system was predicted when the origin of the large circular and linear polarisation of AM Her light was discussed[4]. Two different sources of polarised light were proposed: (1) the optically thick cyclotron or synchrotron emitting accretion column[4–6] and (2) the photosphere of a magnetised degenerate dwarf[7]. In both cases the dwarf's magnetic field was estimated as $\gtrsim 10^8$ G. There is a good agreement between this estimation and the value 3.1×10^8 G following from our interpretation. A study of polarisation in the spectral region near λ3,470 would be required for a positive confirmation. Nevertheless, a short theoretical verification of this identification seems to be necessary.

The cyclotron emission, which is responsible for a cyclotron line, cools the emitting plasma very effectively. The necessary heating may arise from the accretion process when the gravitational energy of the accreted plasma is released near the surface of a compact star. The cyclotron emitting plasma accreted by a

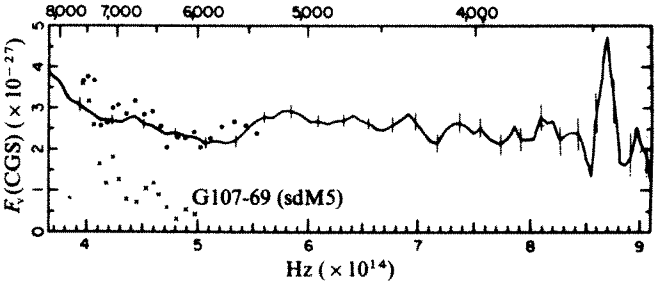

Fig. 1 The spectrum of VV Puppis obtained in April 1977 by Liebert *et al.*[3].

0028–0836/80/020176—02$01.00

magnetised neutron star was considered[8] for the conditions of an X-ray pulsar. The emission features corresponding to cyclotron harmonics were found to be present in the X-ray spectrum. Later the radiation of the accreting degenerate dwarf was considered in more detail[9-12], when the optical depth of the emitting region is sufficiently large with respect to the cyclotron absorption and the optical cyclotron continuum is radiated.

In April 1977, the VV Pup continuum source in 3,500–6,000 Å band was accepted to be the degenerate dwarf's surface with temperature 9,000 K (ref. 3). Therefore, at this low state the shock region was likely to be optically thin for cyclotron radiation and only narrow cyclotron line was radiated. The low luminosity states seem to correspond with the regime of weak accretion. The variations of the accretion result, for example, from the changes of the position of the outflowing star inside the dwarf's magnetosphere. The distance from VV Pup is about 80–150 pc. Using the composite energy distribution[3] one can estimate luminosities $L_{\mathrm{cont}} = (0.5\text{–}2)10^{30}$ erg s^{-1} and $L_{\mathrm{cyc}} = (2\text{–}6)10^{28}$ erg s^{-1} in the low state. It seems natural to assume that nearly all the gravitational energy released was radiated in the cyclotron line. To provide for the observed L_{cyc}, a weak accretion at a rate of $\dot{M} \simeq 3\times10^{11}\,\mathrm{g\,s^{-1}}\ (M_{\mathrm{dwarf}}/M_{\odot})\times(5\times10^{8}\,\mathrm{cm}/R_{\mathrm{dwarf}})$ is necessary (it is the low limit for accretion rate at low state). The radius of the Alfvèn surface seems to be much larger than the distance between the VV Pup's components. This means that the dwarf's magnetic field at every point determines the dynamics of the transferring plasma. Assuming the dipole field configuration, one can estimate the area S of the dwarf's surface where the accretion occurs. If the radius of the outflowing region on the non-degenerate component is of the order of its radius $\sim2\times10^{10}$ cm and the distance between the dwarf and the outflowing region is about 2.5×10^{10} cm, then $S \simeq 5\times10^{15}\,\mathrm{cm}^2$. The supposed cyclotron line should arise in the plasma heated by the standoff shock above this area. What are the conditions necessary for the line origin?

(i) The region of heated plasma should not be optically thick with respect to the cyclotron absorption. The corresponding optical depth in the direction perpendicular to the stellar surface is equal to[13]

$$\tau_{\mathrm{cyc}}(\nu) \simeq (2\pi)^{1/2}\langle nd\rangle\cdot\frac{e^2}{m_{\mathrm{e}}v_{\mathrm{e}}\nu_{\mathrm{B}}}\cdot\exp\left[-\left(\frac{c\Delta\nu}{\sqrt{2}v_{\mathrm{e}}\nu_{\mathrm{B}}}\right)^2\right] \tag{1}$$

where v_{e} is the thermal velocity of the electrons, e and m_{e} are their charge and mass, ν_{B} is the cyclotron frequency and $\Delta\nu$ is $\nu-\nu_{\mathrm{B}}$. The parameter $\langle nd\rangle$ is the mean product of the electron concentration n and the height d of the heated region. The value of v_{e} may be estimated from the condition that the observed mean linewidth is larger that Doppler broadening $\Delta\lambda/\lambda_{\mathrm{B}} \simeq 3\times10^{-2} \geqslant 2v_{\mathrm{e}}/c$. Hence $v_{\mathrm{e}} \leqslant 5\times10^{8}\,\mathrm{cm\,s^{-1}}$ and the electron temperature $T_{\mathrm{e}} \leqslant 10^6$ K. According to equation (1), the heated region is optically thin if $\langle nd\rangle \leqslant 10^{15}\,\mathrm{cm}^{-2}$. It is easy to check that for the cyclotron line all other absorption processes are not as essential as this one. For the equilibrium to set in between the pressure of the infalling plasma $\sim\dot{M}v_{\mathrm{ff}}/S$ and the thermal pressure inside the hot region $\sim2nkT$ it is necessary that $n = 10^{14}\,\mathrm{cm}^{-3}$ for $T = 10^6$ K. Therefore, d should be ~10 cm.

(ii) The plasma heated by the stand-off shock has to provide for the observed luminosity of the cyclotron line

$$L_{\mathrm{cyc}} \simeq \frac{B^2}{4\pi}c\sigma_{\mathrm{T}}\left(\frac{v_{\mathrm{e}}}{c}\right)^2 S\langle nd\rangle$$

$$\simeq 10^{14}\left(\frac{B}{3\times10^8\,\mathrm{G}}\right)^2\cdot\left(\frac{T}{10^6}\right)\cdot\left(\frac{S}{5\times10^{15}\,\mathrm{cm}^2}\right)\quad\mathrm{erg\,s^{-1}} \tag{2}$$

where σ_{T} is the Thomson cross-section of the electron. The value of L_{cyc} estimated from equation (2) agrees with the observed luminosity $\sim10^{29}\,\mathrm{erg\,s^{-1}}$ if $\langle nd\rangle$ is just the same, that is, $10^{15}\,\mathrm{cm}^{-2}$.

(iii) The magnitude of the parameter $\langle nd\rangle$ should be sufficiently large for the shock region to ensure the release of the total gravitational energy. For the Coulomb braking of protons by plasma with concentration $\sim10^{14}\,\mathrm{cm}^{-3}$ it is necessary that $\langle nd\rangle_{\mathrm{Cul}} \simeq 10^{19}\,\mathrm{cm}^{-2}\ (M_{\mathrm{dwarf}}/M_{\odot})^2\times(5\times10^8\,\mathrm{cm}/R_{\mathrm{dwarf}})^2$. This magnitude is too large compared to $10^{15}\,\mathrm{cm}^{-2}$ following from points (i) and (ii) above. However, one should take into account that the proton accretion flow is accompanied (and compensated) by the electron accretion flow. In this case, the braking appears to be much more effective due to the generation of sound and Langmuir oscillations and the interaction with the plasma turbulence[13].

Thus one can conclude that the observed[3] emission feature λ3,470 may be a cyclotron line arising due to the accretion at a rate $\sim3\times10^{11}\,\mathrm{g\,s^{-1}}$ in the heated region with $S \simeq 5\times10^{15}\,\mathrm{cm}^2$, $d \simeq 10$ cm, $n \simeq 10^{14}\,\mathrm{cm}^{-3}$, $T_{\mathrm{e}} \simeq 10^6$ K above the surface of the degenerated dwarf with $B \simeq 3.1\times10^8$ G.

Four implications follow from this conclusion:

(1) Some of the energy emitted in the cyclotron line should be absorbed by the surface of the degenerated dwarf giving rise to a hot spot. To find the exact relation between L_{spot} and L_{cyc} and the continuum spectrum of the hot spot one should solve the problem of radiation transport in the presence of a strong magnetic field and accretion heating. Nevertheless, it seems clear that all the released accretion energy is radiated in the cyclotron line and UV continuum when VV Pup is in the low accretion state (low steady luminosity).

(2) The increase of the accretion rate leads to increasing temperature and concentration in the heated region. It becomes optically thick for the cyclotron line and, as a result, the cyclotron continuum is emitted. The periodic brightening of VV Pup in the active state is thought to be associated with this continuum. Similarly, the increased accretion results in the strong H and He II emission. Thus one may predict an anticorrelation between the periodic brightening and the strong H and He II emission on the one hand, and the presence of the cyclotron line, on the other.

(3) It seems clear from the above discussion that the variation of the cyclotron line with the orbital period 100 min may be expected. It should be brighter in phases corresponding to the brightening in the active state. If there are two active magnetic poles[14] with slightly different magnetic fields, the frequency of the cyclotron line should vary with the phase.

(4) It may be possible to observe the cyclotron line in the AM Her and AN Ursae Majoris spectra when they have low luminosity. The cyclotron frequency is equal to $\nu_{\mathrm{B}} = 2.8\times10^{14}(B/10^8\,\mathrm{G})$ Hz ($\lambda_{\mathrm{B}} = 10{,}700\times(10^8\,\mathrm{G}/B)$ Å). It would also be of interest to search for a cyclotron line in the spectrum of the nova-like MV Lyra. For this star, a small variable linear and circular polarisation of 2% have been recorded[15]. In the spectral observations, the disappearance of the strong H and He II emission was discovered. It may be similar to the disappearance of strong H and He II emission from VV Pup. Thus MV Lyra can be considered as a candidate for the AM Her group.

I thank Professor I. S. Shklovskiy and Drs Yu. N. Gnedin, G. G. Pavlov and R. A. Sunyaev for useful discussions.

Hot hydrogen in the exosphere of Venus

T. E. Cravens, T. I. Gombosi* & A. F. Nagy

Space Physics Research Laboratory, Department of Atmospheric and Oceanic Science, The University of Michigan, 2455 Hayward,
Ann Arbor, Michigan 48109

The Ly α measurements of the hydrogen corona of Venus by Mariners 5 (ref. 1) and 10 (ref. 2) have been shown to be consistent with a two temperature component model. Bertaux *et al.*[3] have successfully fitted the Venera 9 exospheric Ly α data with an elevated (500 K) single temperature; however, they also indicated that their data are not inconsistent with a two component model. Various source mechanisms have been proposed to explain the 'hot' (~1,000 K), energetic component of the hydrogen corona. Here we use recent results from the Pioneer Venus Orbiter (PVO)[4] to establish the major sources of this hot hydrogen population.

The most viable of the suggested source mechanisms were reviewed and re-evaluated by Kumar *et al.*[5], who concluded that the exothermic reaction,

$$O^+ + H_2 \rightarrow OH^+ + H\ (<0.6\ \text{eV}) \qquad (1)$$

is the major source of the 'hot non-thermal' hydrogen. The subsequent recombination of OH^+ produces extremely energetic (~8 eV) hydrogen which makes only an insignificant contribution to the observed hot hydrogen, although it is the major contributor to the non-thermal escape flux.

Kumar *et al.*[5] also indicate that the reaction

$$CO_2^+ + H_2 \rightarrow CO_2H^+ + H\ (<1.17\ \text{eV}) \qquad (2)$$

can also make a modest contribution to the non-thermal population. Sze and McElroy[6] considered the charge exchange reaction:

$$H^+_{\text{hot}} + O \rightarrow O^+ + H_{\text{hot}} \qquad (3)$$

and Kumar *et al.*[5], Chamberlain[7] and Stewart[8] considered:

$$H^+_{\text{hot}} + H \rightarrow H^+ + H_{\text{hot}} \qquad (4)$$

where the hot hydrogen ion could be a solar wind ion or a hot ionospheric ion. These two charge exchange reactions were found to be unimportant for the hot hydrogen population, although reaction (4) was found to contribute to the non-thermal escape flux.

The very comprehensive ionospheric data base, which is now becoming available from the instruments on board the PVO[4] provides a new opportunity for a re-evaluation of the various proposed source mechanisms for the hot hydrogen corona. This letter has two purposes: first, to point out that reactions (3) and (4), as well as (1), are, in light of the PVO results, important sources of hot H from the nightside. Previous studies have never really explained why there was almost as much hot hydrogen observed by Mariner 5 (ref. 1) on the nightside of Venus as there is on the dayside. Ferrin[9] indicated that horizontal transport of hot hydrogen from the dayside might contribute, but he was puzzled by the fact that the nightside non-thermal H seems to be even hotter than the dayside one (1,500 K on the nightside and 1,025 K on the dayside according to Anderson[1]). We will show that the relatively large H^+ and O^+ densities[10] and high ion temperatures[11] (~5,000 K) observed by PVO on the nightside enhance the importance of reactions (3) and (4). Second, we re-evaluate the sources of hot H on the dayside of Venus, in light of the PVO results and conclude that the sources previously proposed are adequate.

Kumar *et al.*[5] calculated column production rates for various potential sources of hot hydrogen to assess their relative importance. To evaluate the hot hydrogen density at the exobase one must take into account collisions of the hydrogen atoms with the cold background gas. Ferrin[9] accomplished this by using Monte Carlo calculations and a multistream approach. He showed, by assuming a hard sphere collision model, that the inclusion of such collisions and the subsequent energy cascading results in significant enhancements of the calculated hot hydrogen densities. In the present work, we used a two stream approach, employed widely in radiative transfer[12] and photoelectron calculations[13], to evaluate the hot hydrogen fluxes and densities on Venus. The equations solved are:

$$\begin{aligned} \langle\cos\theta\rangle \frac{d\phi^+(E,z)}{dz} &= -\sum_i n_i\sigma_i\phi^+(E,z) + \frac{P}{2} + P^+ \\ -\langle\cos\theta\rangle \frac{d\phi^-(E,z)}{dz} &= -\sum_i n_i\sigma_i\phi^-(E,z) + \frac{P}{2} + P^- \end{aligned} \qquad (5)$$

where $\phi^+(E,z)$ is the upward directed hot hydrogen flux; $\phi^-(E,z)$ the downward directed hot hydrogen flux; $n_i(z)$ the i-th scattering atmospheric constituent; z the altitude; σ_i the total scattering cross-section for species i; $\langle\cos\theta\rangle$ the mean of the cosine of the angle of the hydrogen velocity vector with respect to the vertical (assumed to be 0.5, corresponding to an isotropic distribution); P the hot hydrogen production rate due to the various sources under consideration (assumed isotropic); and $P^\pm$ the 'production' rates at a given energy due to cascading from collisions at higher energies.

The energy distribution function, $f(E,z)$, can be determined from the calculated flux values, through the following relationship:

$$f(E,z) = \{\phi^+(E,z) + \phi^-(E,z)\}/v(E) \qquad (6)$$

where $v(E)$ is the hydrogen velocity corresponding to energy E.

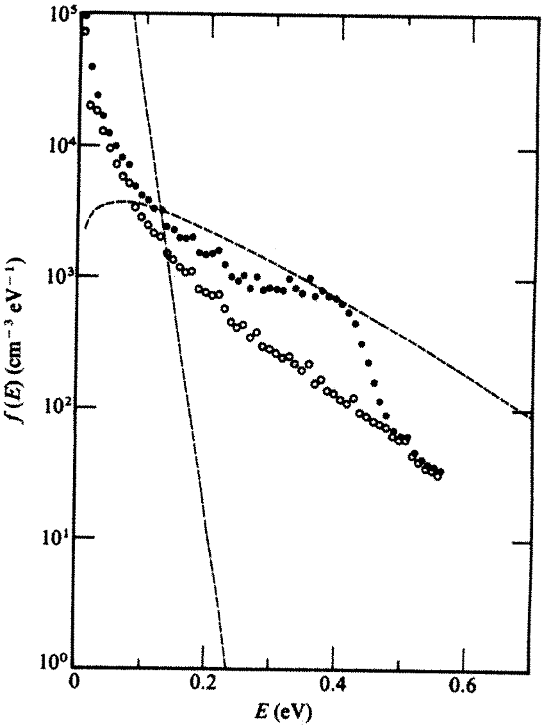

Fig. 1 The total calculated nightside density distribution function (●) is shown. ○, The distribution function including only the charge exchange reactions (3) and (4). The dashed lines represent the two component distribution functions deduced by Anderson[1] ($n = 2\times10^5$ cm^{-3} and $T = 150$ K for the cold and $n = 1\times10^3$ cm^{-3} and $T = 1,500$ K for the hot component).

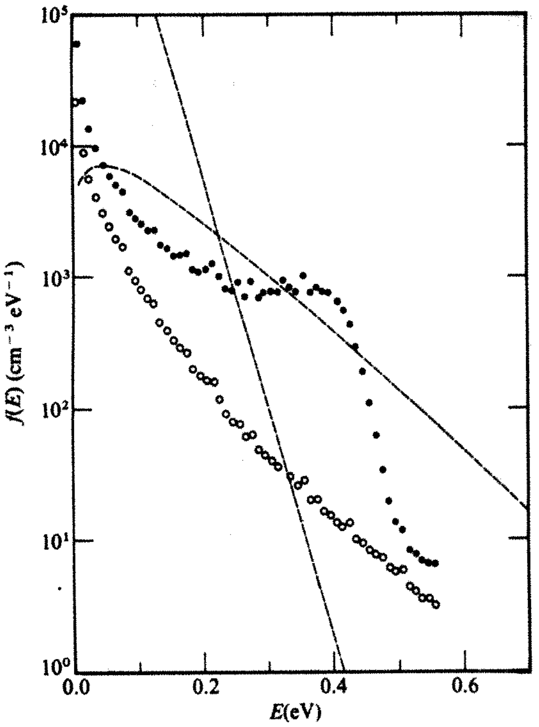

Fig. 2 The total calculated dayside density distribution function (●) is shown. ○, The distribution function including only the charge exchange reactions (3) and (4). The dashed lines represent the two component distribution functions deduced by Anderson[1] ($n = 2 \times 10^5$ cm^{-3} and $T = 275$ K for the cold and $n = 1.3 \times 10^3$ cm^{-3} and $T = 1{,}025$ K for the hot component).

The hot hydrogen atoms were assumed to be 'lost' either by escape at the topside or through a series of energy losses due to elastic hard sphere collisions[14] with the background gases (CO_2, O, H), eventually becoming part of the cold hydrogen population. We have neglected the small but finite probability of energy gain through these collisions. The average energy losses in backward and forward elastic scattering events are[14]

$$\overline{\Delta E_b} = \frac{3mM}{(m+M)^2} E_{in} \quad \text{and} \quad \overline{\Delta E_f} = \frac{mM}{(m+M)^2} E_{in}$$

respectively and where m is the mass of an H atom, M is the mass of the target and E_{in} is the initial H atom energy.

The appropriate neutral gas and ion densities as well as the ion temperatures were taken from Pioneer Venus data[10,11,15], except for the neutral atomic hydrogen densities, for which the Mariner 5 estimate of Anderson[1] was used, and molecular hydrogen, for which the estimate of Kumar and Hunten[16] was used. The adopted values of the dayside Pioneer Venus data correspond to zenith angles of about 70°, while the nightside data correspond to zenith angles of about 140°. The nightside ionospheric data were taken from the outbound segment of Orbit 59. The nightside ionosphere has been found to be extremely variable from orbit to orbit; therefore, the results of these calculations should only be considered as 'representative'.

The energy grid used in the two stream calculations was 0.01 eV and the altitude grid size was variable ranging from 0.2 km below 130 km up to 5 km above 250 km. The upper boundary was at 600 km. To approximate the escaping and ballistic components of the flux, the downward directed flux, ϕ^-, at the upper boundary, was assumed to be equal to the integral of the downward production above this altitude for energies greater than the escape energy (0.56 eV) and equal to the upward flux for lower energies. Although the upper boundary was set at 600 km, scattering by the background gas is not very important above the exobase level which is at about 170 km on the dayside and at about 145 km on the nightside. Consequently, above the exobase (or critical) level the distribution functions calculated using equations (5) and (6) remain almost constant with increasing altitude, because equation (5) only takes into account 'collisional' effects. What we obtain using equation (5) are distribution functions at the exobase level. We assumed that the H atoms from reactions (1) and (2) are produced with less energy than the exothermicities of the reactions would indicate, to take into account some degree of vibrational and/or rotational excitation of the product ions. H atoms from reactions (1) and (2) were assumed to be created with a gaussian distribution; the central energies were taken to be 0.4 eV and 0.8 eV respectively, with an assumed halfwidth of 0.03 eV. The hot H atom densities calculated including the effects of scattering (and cascading) by the background gas are about a factor of three larger than those calculated assuming no scattering and cascading. This is in line with the enhancement values found by Ferrin[9].

Anderson[1] found that he could fit the hot component of Mariner 5 nightside Ly α data by assuming a maxwellian distribution with an exobase density and temperature of 1×10^3 cm^{-3} and 1,500 K respectively. The energy distribution of the total hot hydrogen densities calculated for night-time conditions are shown in Fig. 1; for comparison the contribution due only to reactions (3) and (4) is shown with open circles, and the 'hot' and 'cold' maxwellian components deduced by Anderson[1] are indicated by dashed lines. These calculations indicate that the charge exchange reactions (3) and (4) are the source of about 50% and reaction (1) is the source of the other 50% of the night-time 'hot' hydrogen densities. Overall the calculated distribution function agrees reasonably well both in magnitude and shape with the deduced values in the energy range of 0.12 eV (the crossover point with the cold component) and 0.56 eV (the escape energy). The fact that the calculated distribution is not exactly maxwellian in shape is not of special concern, because the actually observed limb intensities do not uniquely require such a distribution.

The calculated dayside exobase distribution function is shown in Fig. 2 along with Anderson's dayside hot and cold maxwellian distributions. The overall hot density is about the same as the

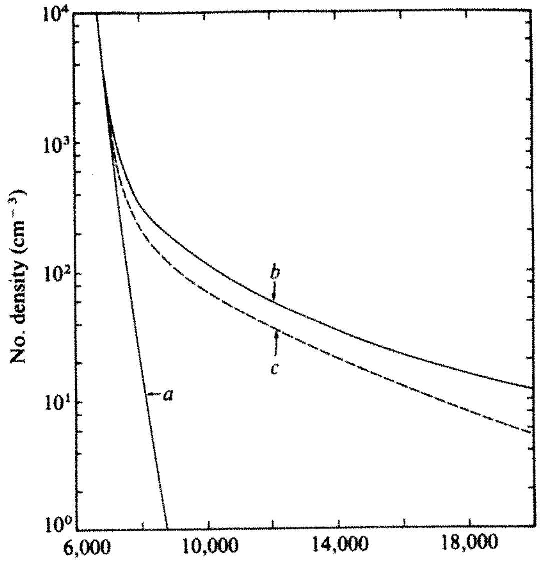

Fig. 3 H number densities for the nightside are shown as functions of the distance from the centre of the planet. a, Corresponds to the cold maxwellian of Fig. 1; b, is for both the cold and hot maxwellians of Fig. 1; and c, is for the cold maxwellian plus the non-maxwellian of Fig. 1.

maxwellian for energies greater than about 0.22 eV and less than 0.57 eV. The charge exchange sources contribute very little to the total hot density on the dayside. The $O^+ + H_2$ reaction is the dominant source of the nonthermal H.

Given a distribution function at the exobase level one can find the corresponding exospheric density distribution of H as a function of altitude by using Liouville's theorem[17]. We calculated the exospheric density distributions, using the distribution functions shown in Figs 1 and 2 and assuming (1) that the distribution functions are isotropic and (2) that there is spherical symmetry. Only ballistic and outgoing (escaping) hyperbolic orbits were included in our calculations. This should be a fairly good assumption because, for Venus, satellite particles will be rapidly removed by charge exchange with energetic solar wind or ionosheath protons. The calculated exospheric densities for the nightside are shown in Fig. 3. The total hydrogen altitude distribution (cold and hot maxwellians), has almost the same shape as density distribution *c* (the cold maxwellian plus our calculated nightside distribution), although the absolute magnitude is somewhat larger. We also calculated the total exospheric altitude distributions for the dayside but do not show them here because of space limitations and because the agreement between our calculated altitude distribution and the one deduced by Anderson[1] agree even better (~20%) than shown for the nightside case.

Note that, in comparing the results of these calculations with the Mariner 5 data, the atmospheric and ionospheric conditions were different during the Mariner 5 encounter and the Pioneer Venus observations and furthermore, the ionospheric densities are highly variable and only model values of H_2 are available. The calculations presented here indicate, within the limitations just mentioned, that reactions (1), (3) and (4) are the major sources of the 'hot' component of Venus hydrogen corona. On the nightside the charge exchange reactions are important because the ion temperatures are high and the H^+ densities are greater than on the dayside. There are preliminary indications, from the Pioneer Venus ion mass spectrometer results[10], that there is a significant night-time hydrogen bulge; if the night-time 'cold' hydrogen densities are greater than the values assumed in these calculations, the importance of reaction (4) will increase further. Contrary to earlier suggestions[9], most or at least a significant fraction of the nightside hot hydrogen population is apparently produced locally.

As the Pioneer Venus Ly α intensity results become available, more quantitative comparisons can be carried out. The nightside Venus ionosphere is highly variable, with apparent time scales of the same order as the hot hydrogen lifetime (~10^3 s) and therefore, orbit to orbit comparisons between the measured Ly α intensities and ionospheric parameters can be used to check the validity of the basic mechanisms suggested in this work.

A weak interaction model for Io and the jovian magnetosphere

W.-H. Ip & W. I. Axford

Max-Planck-Institut für Aeronomie, D-3411 Katlenburg-Lindau 3, FRG

Four features of the interaction between the satellite Io and the surrounding jovian magnetosphere place constraints on the atmosphere of the satellite and on the nature of the interaction: (1) the atmosphere must be at least partly an exosphere so that sodium and other non-volatile atoms sputtered from the surface of the satellite could escape[1,2]; (2) the atmosphere should be dense enough for a detectable ionosphere to form showing a leading–trailing asymmetry[2,3]; (3) the atmosphere should provide an electrically conductive path to produce the electric currents which eventually cause the Io-related decametric radio emissions[4,5]; (4) the conductivity of the ionosphere should not be large enough to short out the electric field seen by the satellite, as pronounced absorption of energetic particles is observed[6–8]. Before the Pioneer 10 encounter it was pointed out[9] that erosion by the co-rotating magnetosphere caused atmospheres on the galilean satellites with surface pressures in the range 10^{-5}–10^{-9} mbar, if they exist, to be stable only if they are continuously replenished and therefore likely to be associated with "venting or the presence of non-hydrous ices on the surface". Alternatively, if the surface is covered with non-volatiles and/or water ice, the atmospheric pressure would be very low and controlled by sputtering due to the impact of magnetospheric plasma and energetic particles on the surface[9]. In any case, the interaction with the magnetosphere is likely to be 'weak' as it is for Mercury[10], that is, the magnetic field and plasma sweep into and past the satellite being affected mainly by the additional inertia of newly formed ions (provided the satellite is non-conducting and non-magnetic). We substantiate these arguments here using the recent Voyager observations, and suggest that the interaction between Io and the magnetosphere can be understood if the atmosphere of Io were largely exospheric in nature and controlled by the vapour pressure of SO_2 ice which covers the surface.

The discovery of volcanic activity on Io by Voyager 1 (ref. 11) confirms that venting of gas from beneath the surface must be an important source of gas in the atmosphere. By analogy with the gaseous products of terrestrial volcanoes (ignoring the H_2O and N_2 which probably have an external origin) one might expect CO_2 and SO_2 to predominate together with smaller amounts of SO_3, H_2S, CO, A, He, H_2 and Cl_2 (ref. 12). The behaviour of such volatiles, if ejected from the volcanoes on Io, can be studied in terms of a vapour pressure versus temperature diagram as shown in Fig. 1. Evidently CO_2 and several other possible constituents such as CH_4, CO and N_2 have such high vapour pressures that they would tend to completely dominate the atmosphere if they were present in the volcanic ejecta in any significant amounts. However, Voyager 1 observations of energetic heavy ions in the jovian magnetosphere indicate that S and O ions are dominant and C and N ions (other than those of obviously solar origin) are essentially absent[8]. Furthermore, SO_2^+ ions and their dissociation products were detected by the plasma experiment[13] and an SO_2 absorption feature was identified on the surface of the satellite by the IR and radiometry experiments[14]. Accordingly, we conclude that the gaseous emission from the Io volcanoes is almost entirely SO_2 and that the other components commonly found in terrestrial volcanoes are absent or very depleted.

To understand how this would affect the atmosphere of Io we should consider the situation where the surface of the satellite is uniformly covered with SO_2 frost and the atmospheric pressure is determined locally by the surface temperature (the effects of

0028-0836/80/020180—04$01.00

pressure gradients in inducing lateral flows are neglected). Figure 2 shows that the pressure should vary from ~1.3 × 10^{-3} mbar on the equator at the subsolar point ($T = 140$ K) to an exospheric level ($<2 \times 10^{-8}$ mbar) at elongations exceeding 80° from the subsolar point ($T < 100$ K). This maximum pressure exceeds the upper limits obtained from occultation measurements[15] but as these only apply to the limb, a detectable atmosphere would not be expected. The major constituents of the atmosphere should be essentially frozen out on the dark side of the satellite and over the whole surface during eclipses. However, ^{40}Ar, He and H_2, all of which could be expected to be present in volcanic ejecta in small amounts, could in principle survive such low temperatures and would provide most of the atmosphere in such situations. The argon could conceivably condense very close to the poles of Io and consequently have a very low average vapour pressure. This is not possible for hydrogen and helium. The evaporative and magnetospheric losses of these constituents must be severe enough to prevent them from becoming dominant. In fact, the ionisation time scale in the hot dense plasma which constitutes the magnetospheric environment of Io is sufficiently short (less than the orbital/rotation period of the satellite) that there is little chance for these constituents to accumulate. Similarly, secondary products such as O_2, which could be produced as a result of photolysis[16] or the effects of energetic magnetospheric particles, would also be lost rapidly.

We now consider the interaction between the magnetospheric plasma and magnetic field and the atmosphere of Io and in particular the abovementioned constraints on the interaction. The approximately exospheric (column content $\leq 10^{15}$ cm^2) nature of the atmosphere shown in Fig. 2 allows for the direct escape of sputtered material over a large part of the surface. As pointed out by Johnson *et al.*[2] a relatively dense 'ionosphere' can be produced in such a rarified atmosphere if the ionisation is due to the presence of a flux of relatively soft (10–10^2 eV) electrons, which are known to exist in the magnetospheric plasma torus (refs 3, 18, and H. E. Johnson and W. I. A. unpublished data). However, much of the ionosphere may not be as significantly affected by recombination as assumed by these authors because the convective removal time is shorter than the dissociative recombination time except in regions where the plasma density is $\gg 10^5$ cm^{-3} or the atmosphere is sufficiently dense to prevent rapid motion of the plasma. In these circumstances, the plasma density is controlled by convection giving rise to the leading–trailing asymmetry observed at the limb[3]. Obviously, over the subsolar point where the atmospheric density is large, the structure of the ionosphere must be much more complex and depends on the orbital phase of Io.

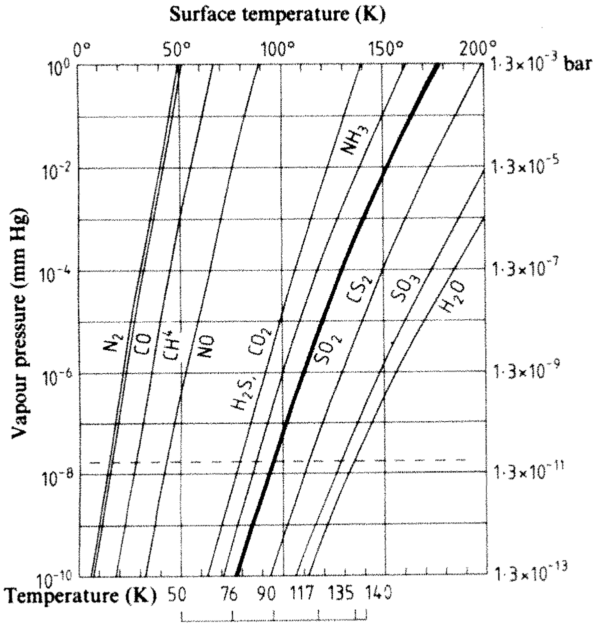

Fig. 1 The vapour pressures for various possible atmospheric constituents of Io as function of surface temperature. The curves are extrapolated from the data of refs 36, 37. The upper limit of the surface pressure determined by stellar occultation measurement is $\approx 10^{-4}$ mbar (ref. 15); and the broken line marks the exospheric limit of 3×10^{-8} mbar. The surface temperatures at various latitudes (θ) with a $(\cos \theta)^{1/4}$ dependence are marked in the bottom of the diagram.

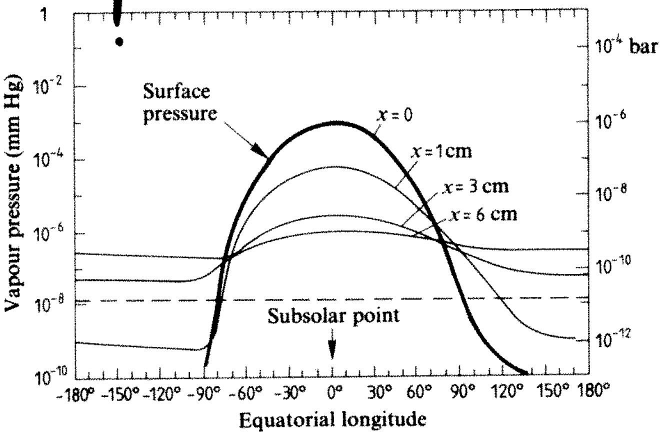

Fig. 2 The variations of SO_2 vapour pressure on Io as a function of longitude from the subsolar point. The curve for $x = 0$ is approximated from the numerical results of Sinton[38] and the curves for $x \neq 0$ are derived by assuming the surface material has thermal inertia 1.3×10^4 erg cm^{-1} s^{-1} K^{-1}, heat capacity 10^7 erg K^{-1} g^{-1}, a density of 0.1 g cm^{-3}, and thermal conductivity 1.7×10^2 erg cm^{-1} K^{-1} s^{-1}. Differing values of x correspond to differing thicknesses of a fine dust layer which could conceivably exist on parts of the surface at least.

As the atmosphere of Io is mainly exospheric the interaction with the magnetosphere is correspondingly weak except in the vicinity of the subsolar point where the surface pressure is relatively large. This implies that the incident magnetic field lines to a large extent cross the satellite relatively freely and the energetic particles they carry with them can suffer absorption on the surface as required by the observations[7,8]. However, the interaction should be capable of producing a fairly large electric current (~10^6–10^7 A) to account for the Io-related decametric radio emissions. That is, a drag must be exerted on the corotating plasma and the magnetic field correspondingly stressed, so that a disturbance in the form of an Alfvén wave propagates in both directions along the field lines towards the planet[4,5,19]. This could be to a large extent the result of ion–neutral collisions (Pedersen conductivity) in the dense atmosphere surrounding the subsolar point, in which case a very strong longitudinal control of the radio emissions might be expected. However, note that the effect of ion mass pick-up, which has previously been overlooked in this connection (although alluded to in ref. 9)), could make a significant if not dominant contribution in this respect.

The effects of ion mass pick-up in the presence of a magnetic field have been considered in contexts other than the Io–magnetosphere interaction, notably the interaction between the solar wind and comets[20,21], the ionospheres of Mars, Venus and Mercury[22–25] and the interstellar gas[26,27]. The processes involved can be understood using the mass and momentum conservation equations for the plasma which are good approximations in the circumstances of interest here:

$$\frac{\mathrm{d}n}{\mathrm{d}t} = q \tag{1}$$

$$\frac{\mathrm{d}}{\mathrm{d}t}(nmV) = nm\frac{\mathrm{d}\mathbf{V}}{\mathrm{d}t} + mq\mathbf{V} = \mathbf{j} \times \mathbf{B} \tag{2}$$

$$\mathbf{E} + (\mathbf{V} + \mathbf{B}) = \mathbf{j} \times \mathbf{B}/ne \tag{3}$$

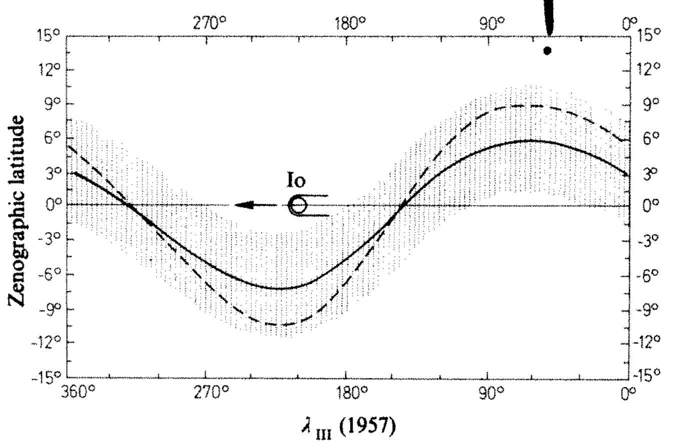

Fig. 3 Geometrical relationship between the corotating thermal plasma disk and the orbital position of Io. The shaded region represents the sulphur ion nebula with thickness equal to one jovian radius[32–34]. The solid curve indicates the central plane of the plasma disk, and the broken line the magnetic equator according to the Goddard Space Flight Center O_4 magnetic field model[35]. The direction of motion of Io in the rotating frame of the jovian magnetosphere and the convection pattern of the ionospheric plasma are also sketched. A current directed outward from Jupiter is generated in the extended atmosphere of Io to accelerate the newly created satellite ions into corotational motion. Io periodically crosses the plasma disk/magnetic equator at System III longitudes $\lambda_{\rm III} \approx 120°$ and 315°.

n is the plasma density, $\mathbf{V}$ is its velocity, m is the mean ion mass, q is the effective source strength due to ionisation of neutrals, $\mathbf{E}$ is the electric field, $\mathbf{e}$ the charge on an electron, and $\mathbf{j}$ and $\mathbf{B}$ are the electric current and magnetic induction respectively. As a first approximation, we neglect the effects of plasma pressure gradients and ion-neutral collisions and note that q must be proportional to the neutral density N regardless of the ionisation process. These equations, together with Maxwell's equations and suitable boundary conditions, determine the behaviour of the plasma. The two terms on the left of equation (2) can be regarded as sources of electric current, the first of which involves the deceleration and acceleration of the plasma (that is the polarisation current) and the second describes the effects of mass loading due to pick-up or loss of plasma by ionisation of neutrals and recombination or absorption, respectively. The latter term is negligible in most ionospheric situations but not in the case under consideration.

Taking $q = \alpha N$ with α and also $\mathbf{V}$ constant to a first approximation, we find from equation (1) that

$$\begin{aligned} n' &= (\alpha N_0 H/V)\exp(-z/H) \text{ upstream} \\ &= \alpha N_0 H/V(1-\exp(-z/H)) \text{ downstream} \end{aligned} \qquad (4)$$

where n' is the additional plasma density produced by ionisation of neutrals, z is the height above the surface of Io (for normal incidence), and N_0H is the column content of the atmosphere. These solutions are, of course, highly idealised but they demonstrate certain basic features of the interaction, notably the upstream–downstream asymmetry and the relationship between the scale heights of the ionosphere and neutral atmosphere. To produce the additional plasma density of $5\times10^3\ \text{cm}^{-3}$ observed on the upstream side of Io by Pioneer 10 (which, as it used a refraction technique, was unable to detect the uniform ambient magnetospheric plasma) α must be $2.5\times10^{-5}\ \text{s}^{-1}$ for $N_0H \approx 10^{15}\ \text{cm}^{-2}$.

Clearly it is not easy to predict the form of the electric current distribution resulting from such an interaction as it requires a knowledge of the precise form of the flow field as well as the sources and sinks of plasma and if full three-dimensional treatment is warranted. However, one can estimate the magnitude of a typical component of the current associated with mass pick-up (equation (2)) as simply

$$I = \dot{M}V/BL \qquad (5)$$

Here $\dot{M}$ is the total mass picked up by the magnetosphere and L is a length which is of the order of the diameter of Io. We estimate that if $\dot{M} \approx 2.5\times10^5\ \text{g s}^{-1}$ on the upstream side of Io then with $V = 57\ \text{km s}^{-1}$ and $L = 4{,}000$ km, the corresponding electric current induced is $I \approx 2\times10^6$ A. For the whole interaction, including the downstream region, the electric current may be significantly larger. The effective ionospheric conductance associated with ionisation of the exosphere is $\Sigma = I/EL \approx 5$ S and the energy dissipation is $IEL \approx 8\times10^{18}\ \text{erg s}^{-1}$. Note that the effects of the inertial term on the left hand side of equation (2) tend to reduce the current density on the upstream side of the satellite where the plasma decelerates by a factor of order $(1+X^2)^{1/2}$ where $X = \omega L'/V$, L' is a characteristic length, and ω is the gyrofrequency of the newly created ions in the ambient magnetic field. This reduction is significant on the upstream side as $L' \approx H$ and $X \approx 1$, but there is no diminution of the current overall as all the freshly produced ions must be accelerated eventually up to the corotational speed of the magnetosphere relative to Io. It can be seen that equation (5) also applies to the Io torus of more extensive structure.

All aspects of the interaction between Io and the jovian magnetosphere can, therefore, be accounted for if the atmosphere has the properties indicated in Fig. 2 and we suggest that ion mass pick-up is an important ingredient of this interaction. These arguments lead to some interesting conclusions on the variation of the nature of the interaction with both the jovian longitude and the Io phase. As the dense regions of the atmosphere influence the interaction the phase of Io in its orbit must be important as, for example, the subsolar point is on the leading–trailing side of the satellite at western–eastern elongations respectively. Also the fact that the jovian plasma sheet is not coplanar with the orbit of Io (see Fig. 3) should lead to a jovian longitudinal control of the currents produced by the interaction if the total ionisation rate is the determining factor and this is controlled by the density of the corotating magnetospheric plasma. Note that the plasma torus need not instantaneously coincide with the equilibrium position shown since it can oscillate in position along the magnetic field with a frequency $\sqrt{3}\Omega/2\pi$, where $2\pi/\Omega$ is the rotational period of Jupiter. This is not commensurate with the (relative) orbital period of Io and hence the addition of fresh plasma with random phase will tend to supress the oscillations. Nevertheless, the oscillatons should be completely absent only at longitudes $\lambda_{\rm III} \approx 120°$ and 350° where Io crosses the jovian magnetic equator.

We thank Drs M. Acuña, V. M. Vasyliunas, C. K. Goertz and John Pearl for useful conversations.

Note that several of our conclusions have been reached independently in papers submitted later than our original manuscripts. In particular, we refer to the discovery of SO_2 gas on Io by Pearl *et al.*[28] and the identification of SO_2 frost on the surface by Fanale *et al.*[29]. Smith *et al.*[30], Pearl *et al.*[28] and Kumar[31] have also drawn attention to the fact that the atmosphere of Io should be spatially inhomogeneous.

Accretion of nitrogen during the growth of planets

John F. Kerridge

Institute of Geophysics, University of California, Los Angeles,
California 90024

The ^{15}N/^{14}N ratio measured in nitrogen of the terrestrial atmosphere is, or was, apparently widespread in the inner Solar System. Such an observation might suggest that this value (3.61×10^{-3}) represents that of proto-solar material. However, I argue here that the original ratio was at least 20% lower, the presently observed value having resulted from significant isotopic fractionation, presumably caused by nebular condensation processes.

First, I will summarise what we know about ^{15}N/^{14}N of inner Solar System objects, expressing these values as per cent deviations from the terrestrial atmospheric value. The Moon is highly depleted in volatiles, and identification of indigenous lunar N, free from either terrestrial contamination or cosmic ray spallation products, has consequently been very difficult. The best estimate for the lunar ^{15}N/^{14}N ratio is between +1 and +4% relative to air[1].

The martian atmosphere is highly enriched in ^{15}N, about +62% relative to air[2]. However, it has been argued that this value has resulted from selective escape of ^{14}N from the martian upper atmosphere[2]. When allowance is made for this fractionation, a starting composition close to the terrestrial value is derived[2]. Because of the model dependence of the fractionation calculations, it is not possible to assign realistic uncertainty limits to the initial ^{15}N/^{14}N ratio. A large uncertainty is also associated with the ^{15}N/^{14}N ratio found for the atmosphere of Venus. The value measured by Pioneer Venus is within 20% of that of terrestrial air[3].

Different groups of stony meteorites have significantly different N isotopic compositions[4,5], although the actual nature of the relationship between ^{15}N/^{14}N ratio and chemical–petrographic classification is unclear. Referring to Fig. 1 of ref. 5, ordinary chondrites and carbonaceous chondrites of petrologic types 3 and 4 lie close to the terrestrial value (−0.3 to +2.0% and −4.3 to +0.2%, respectively). Carbonaceous chondrites of petrologic types 1 and 2 are enriched in ^{15}N by up to 4.6% (with one large anomaly, Renazzo, at +17.2%), the degree of enrichment roughly correlating with increasing N content[5]. Enstatite chondrites, on the other hand, are depleted in ^{15}N (to −4.3%), with a rough tendency for ^{15}N/^{14}N to decrease with increasing N content[5]. Whatever the cause(s) of these isotopic patterns, the trend of the meteoritic data suggests that the present compositions reflect fractionations, in different directions, of a starting composition close to that of the terrestrial atmosphere. Apparently, formation of organic matter in carbonaceous chondrites and inorganic nitrides in enstatite chondrites favoured heavy and light isotopes, respectively.

This picture of isotopic uniformity in the inner Solar System is disturbed when we turn to the only other repository of N analysed so far: the solar wind, believed to represent the composition of the solar convective zone[6]. These analyses have been made using solar wind ions implanted in the lunar surface during the past 4 Gyr, and have revealed that ^{15}N/^{14}N in the Sun has increased substantially over the lifetime of the Moon[7]. The actual magnitude of the change is still not established precisely but is known to be at least 30%, from −19% (ref. 8) to +11% (ref. 1) relative to air. Whatever the cause of this change, possibly nuclear reactions in the solar convective zone[7], it seems clear that the solar atmosphere must have had an initial ^{15}N/^{14}N ratio at least 19% lower than terrestrial air. It is therefore difficult to avoid the conclusion that this lower value must also have characterised the proto-solar nebula. This in turn leads to the conclusion that the value observed or inferred for the Earth and other planetary objects must represent the result of significant isotopic fractionation.

It is unlikely that we can specify, at this time, how such fractionation occurred. The fact that its magnitude was apparently independent of either the size of the planetary object (radii varying from some tens of kilometres[9] to more than 6,000 km) or its degree of volatile depletion (from about 10^{-7} to 10^{-3} g N per g) suggests that N, and presumably other volatiles, were accreted by early forming planets, and planetesimals, in the form of a solid component of volatile-rich condensate. Isotopic fractionation apparently took place between this component and the reservoir from which it condensed, rather than during accretion. The magnitude and sign of the fractionation suggest gas–solid equilibration at very low temperature rather than kinetic effects or isotopically selective loss of gas.

Because neither the nature of the N-rich condensate nor its temperature of formation is known, it is not possible to determine whether the fractionation factor associated with the condensation reaction(s) is adequate to provide the degree of fractionation implied here. Calculated fractionation factors[10] for isotopic exchange between simple N compounds imply an equilibration temperature significantly below 273 K. Equilibration at such low temperatures in the nebula seems intuitively unlikely but similar temperatures are suggested by the enrichment of the Earth and carbonaceous chondrites in deuterium, relative to its abundance in the primitive solar nebula[11–13].

The condensation/accretion scenario suggested here is qualitatively consistent with the model of Anders and Owen[14], which proposes acquisition of the Earth's volatiles via a veneer of composition similar to that of carbonaceous chondrites of petrologic type 3, which also provide a reasonable match in ^{15}N/^{14}N ratios[5]. However, the magnitude of the fractionation suggested here, between the volatile-carrier and its parental reservoir, implies a temperature of formation significantly lower than the 400–450 K inferred by Anders and Owen for carbonaceous chondrite material[14].

The hypothesis presented here is potentially testable as it leads to three observational predictions. First, the ^{15}N/^{14}N ratio in Jupiter, which should directly reflect that of proto-solar material, will be found to be at least 19% lower than terrestrial air. Second, the ^{15}N/^{14}N ratio in the present solar wind will be found to be about 11% greater than in air (more if we do not measure it soon). Third, isotopic fractionation of N during condensation may have been accompanied by similar fractionation of any other volatile elements condensing at the same time. If such elements, or the appropriate fractions of them, can be isolated for analysis, similar heavy isotope enrichments may be detected. In fact, the deuterium mentioned above may constitute such evidence; however, the relationship between the provenance of nitrogen and that of hydrogen in early Solar System objects remains a topic for further study.

Dynamical test of the law of gravitation

Hiromasa Hirakawa, Kimio Tsubono & Katsunobu Oide

Department of Physics, The University of Tokyo, Bunkyo, Tokyo 113, Japan

Although well established in the realm of celestial mechanics, gravitation between two masses has not yet been thoroughly examined in a laboratory. There have been several tests of the interaction since the Cavendish's celebrated experiment[1–6], most of them measuring the static attraction between two spherical masses at a distance R less than 0.8 m. The gravitational interaction is weak and, in contrast with the electromagnetic interaction, there is no effective means to shield it. It has therefore proved difficult to increase the distance R over 1 m. Under the circumstances several authors[7–9] have noted that the existing experimental data do not exclude a possible term which is added to the newtonian $1/R$ potential. Meanwhile, on the grounds of elementary particle physics, a number of theoretical papers[7,10–14] have been published predicting additional terms which vanish rapidly at $R = \infty$. We now report a test of the law of gravitation in a range of R up to 4.2 m. The experiment is based on a low frequency dynamical quadrupole–quadrupole interaction between two masses, which was first observed by Sinsky and Weber[15,16]. Our result agrees with the inverse square law within the accuracy of the experiment.

A steel bar of length $b = 0.52$ m and mass $m = 44$ kg was rotated in a horizontal plane at frequency $f = 30.3$ Hz and the resulting dynamic gravitational field was measured by a mass quadrupole antenna[17] resonating at $2f = 60.5$ Hz (Fig. 1). The antenna is a 1,400-kg aluminium square plate with cuts on each side, contained in a vacuum tank of a constant temperature, $T = 308$ K. The oscillation of the antenna was sensed by an electrostatic transducer of field strength 4.6×10^6 V m^{-1} mounted inside one of the cuts. The quality factor Q of the unloaded antenna was 65,000 at 60.5 Hz. The resulting width of the resonance, 9.3×10^{-4} Hz, was inconveniently narrow for a long-term operation requiring a precise frequency tracking. Therefore we applied a cold damping[18] to the antenna, loading it with an artificial cold resistor[19], 6.3 MΩ at 3.0 K. This resulted in a reduced quality factor $Q' = 4{,}100$, a resonance width 1.5×10^{-2} Hz, and a noise temperature $T' = 22$ K of the antenna. With the rotor located at $R = 2.2$ m, the antenna oscillated with an amplitude $x = 1.9 \times 10^{-13}$ m in regard to the transducer displacement. This yielded a coherent 8.7×10^{-7} V (peak) transducer output, while the background noise, consisting mostly of the antenna brownian motion at $T' = 22$ K, was 1.2×10^{-8} V (r.m.s.).

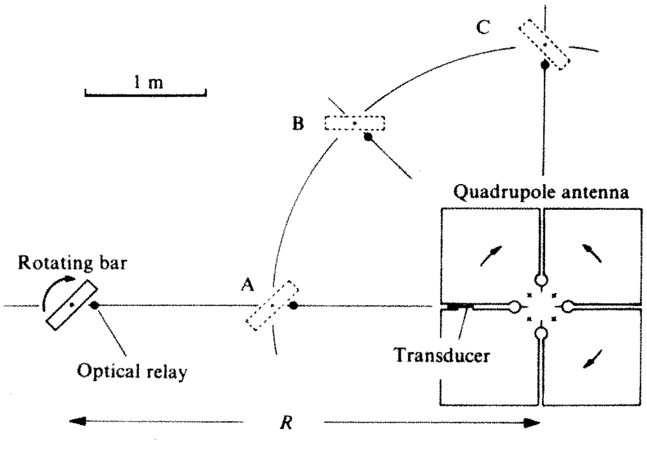

Fig. 1 Dynamic gravitational field of a 44-kg steel bar rotating at 30.3 Hz was measured by a 1,400-kg aluminium quadrupole antenna resonating at 60.5 Hz. Signals were obtained for a distance R up to 4.2 m.

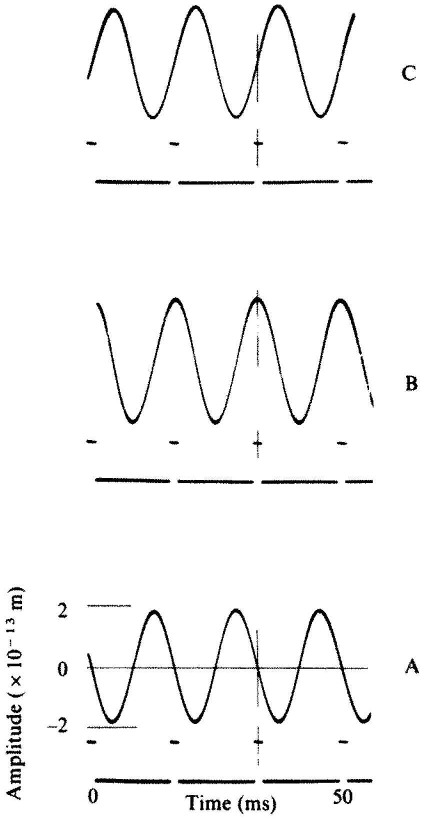

Fig. 2 Oscillation of the antenna observed on a cathode-ray tube with the rotor located at A, B and C of Fig. 1 respectively. Distance $R = 2.2$ m. The timing pulses obtained from an optical relay indicate the rotation angle of the bar. Note the difference in the phase of oscillation in three pictures. The signal at B is slightly larger than the others, showing the effect of the higher mass multiple moments of the antenna. With an increasing distance R, the ratio of the signal B to signal A (=C) tends to 16/19.

To eliminate a possible interaction of the antenna with coherent noises in the background, we rotated the bar in a steel vacuum tank using a plastic chain and two sprocket wheels of a teeth ratio 8/5. The larger wheel was mounted on a common shaft of a 400-W induction motor and a phase-locking 200-W synchronous motor, the latter being driven by a 37.8-Hz three-phase power supply connected to a quartz frequency synthesiser. In spite of these measures, we noted a coherent magnetic field around the tank, 10^{-4} G at 60.5 Hz and a smaller amount at 30.3 Hz, presumably originating from a geomagnetic or remanent magnetisation of the rotating steel bar. We checked, however, that a magnetic field, 5 G at 60.5 Hz, more than 90 db above the background was needed to produce a

0028-0836/80/020184—02$01.00

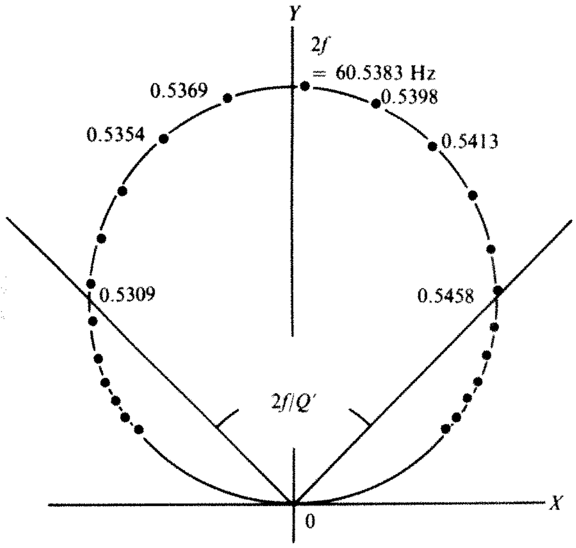

Fig. 3 · Characteristics of the antenna resonance at 60.5 Hz. The amplitude and phase of the forced vibration of the antenna is given as a function of the frequency $2f$ of the oscillating field. Quality factor of the antenna was reduced to $Q' = 4{,}100$ by application of a cold damping.

spurious antenna output of the same size as the observed signal. The rotor also caused vibration of the laboratory floor at 60.5 Hz. Two decks of pneumatic isolation pads were inserted below the rotor tank. They were more than enough to eliminate the contamination of the signal through this channel. In fact no change of signal was noted when one of the decks was removed.

The behaviour of the mass quadrupole antenna in the gravitational field of the rotating bar obeys an equation of forced motion of a damped linear oscillator quite well. The amplitude of vibration is given by

$$x = \frac{\gamma G a Q' m b^2}{R^5 f^2}$$

where a is the size of the antenna. γ is a numerical coefficient which depends on the geometry of experiment including the shape, the size, and the relative orientation of the masses. Figure 2 shows the antenna output signal obtained with the rotor at three locations around the antenna. The timing signal indicating the angle of the bar is also shown. The characteristics of the antenna resonance are given by a circular locus of Fig. 3 showing the observed amplitude and phase of vibration as a function of the frequency $2f$ of the oscillating field. The signal decreases with increasing distance R as $1/R^5$. However the signal-to-noise ratio can be improved substantially by means of Fourier integration[20] of the antenna output with the rotor timing signal as a reference. Thus we obtained a signal at $R = 4.2$ m, 30 db above the brownian motion, with an integration time of 4 h. Figure 4 compares the observed signal and the expected signal based on the inverse square law, with the distance R as a parameter. This result confirms Newton's law of gravitation within the range and accuracy, ±3%, of the experiment. For a parameter δ in an assumed form, $1/R^{1+\delta}$, of the potential, we have obtained 0.000 ± 0.053.

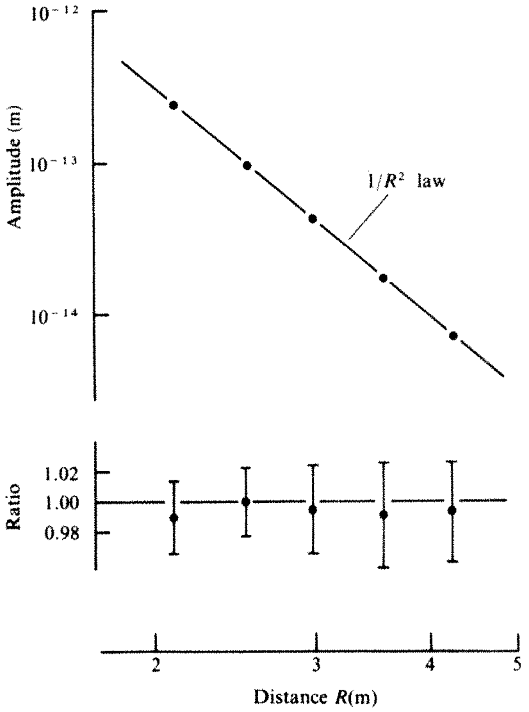

Fig. 4 The observed and calculated intensities of the signal and their ratio as a function of the distance R. The scale of the observed signal is normalised to the calculated signal at $R = 2.5$ m. The calculation is based on the inverse square law of gravitation. The effect of the higher multipole moments, the finite size of the rotor and the antenna, is taken into account by a numerical integration over the masses.

We thank Mr H. Yoshikawa for construction of the rotor. This work was supported by a grant from the Mitsubishi Foundation.

Stress corrosion cracking of biotite and feldspar

R. L. Barnett & R. Kerrich

Department of Geology, University of Western Ontario, London, Ontario, Canada N6A 5B7

Pervasive intragranular cracking of biotite and feldspar has been observed in a naturally deformed granodiorite, where the leading edge of cracks are sites for specific reactions of parent grains to secondary mineral products. This textural feature provides evidence for an interrelationship of chemical reactions to slow crack propagation, and is considered to be a natural example of stress corrosion cracking. It is probable that the mineral reactions are catalysed by increase of the stress intensity at fracture tips, with reaction rates controlling propagation of the fractures.

(1) Orthoclase parent grain with fractures containing secondary fibrous orthoclase (2). Values in parentheses represent one standard deviation. (3) Albite parent grain with both secondary orthoclase (4) and albite (5) fracture fillings. (6) Oligoclase parent grain with secondary orthoclase (7) in fractures. (8) Parent oligoclase grain with abundant fine grained sericite, recrystallising to a less calic, sericite-free plagioclase at the leading edge of (10) and within fractures (9). Also present in the oligoclase parent grains are fractures containing secondary orthoclase (11).

The process of stress corrosion cracking has been reviewed by Anderson and Grew[1]. Slow crack growth at subcritical stress intensities by stress corrosion contrasts with fast irreversible propagation of 'Griffith cracks' above the critical stress value for brittle failure. Subcritical crack growth has been extensively studied in metals and ceramics[1–4]. Time-dependent cracking of quartz and granite has been experimentally demonstrated by Martin[5] and Wilkins[6] respectively, and slow growth of microfractures implicated in a number of geological phenomena such as pre-faulting dilatancy and magmatic intrusion[1].

However, we are not aware of any previous descriptions of chemical reactions accompanying cracking in naturally deformed rocks, or an identification of the reactions involved. The rocks to be described which exhibit intragranular fracturing accompanied by mineral reactions are located at the boundary of a major subvertical shear zone which transects granodiorite basement of the Aiguilles Rouge Massif, at Miéville, Switzerland. The granodiorite consists of orthoclase and plagioclase (~An_{25}–An_{18}) feldspar phenocrysts (45–60%), quartz (25–30%) and biotite (10–30%) as essential minerals. At increasing states of deformation the primary minerals are progressively reduced in grain size by a factor of 100–1,000 through microfracturing and recrystallisation. Accompanying the deformation is production of secondary albite, chlorite, epidote, calcite, ilmenite and sphene. The ambient temperature of cracking is estimated to be <250 °C from (1) the presence of prenhite–

pumpellyite facies cover rocks to the basement, which are involved in the shear zone[7], and (2) filling temperatures of 180–210 °C determined on primary fluid inclusions in feldspar fracture fillings. These represent minimum values inasmuch as corrections to temperature cannot be applied without precise knowledge of the hydrostatic pressure and fluid composition. However, corrections are probably less than +40 °C.

In rocks at a low state of deformation grains of biotite have intragranular fractures with a linear to sigmoidal shape which are bounded by an envelope of pale brown birefringence. This region corresponds to a decrease of Ti and increase of Fe relative to the composition of grains in areas unaffected by cracking. Fracture openings are occupied by secondary minerals, predominantly ilmenite, low-Ti biotite and high-Ti muscovite (Table 1). The presence of titanium in muscovite may be due to ultrafine grained disseminated ilmenite. These mineral products were also observed in kink bands, and at grain boundaries where the parent biotites have recrystallised, but are not present at grain boundaries in undeformed rocks. Parent grains and secondary products were examined using electron microprobe. Randomly orientated ilmenite grains (~10 μm long) are present up to 200 μm ahead of the leading edge of fractures (Fig. 1*a*). This region is characterised by the initiation of mineral reactions, and represents the first stage of chemically controlled disruption of the biotite structure where increase of the stress intensity at fracture tips may enhance lattice diffusion and thus catalyse reaction of the primary biotite. Decrease of volume accompanying the reaction of biotite to ilmenite plus muscovite in cracks may also serve to increase the local stress intensity at fracture tips, and enhance permeability.

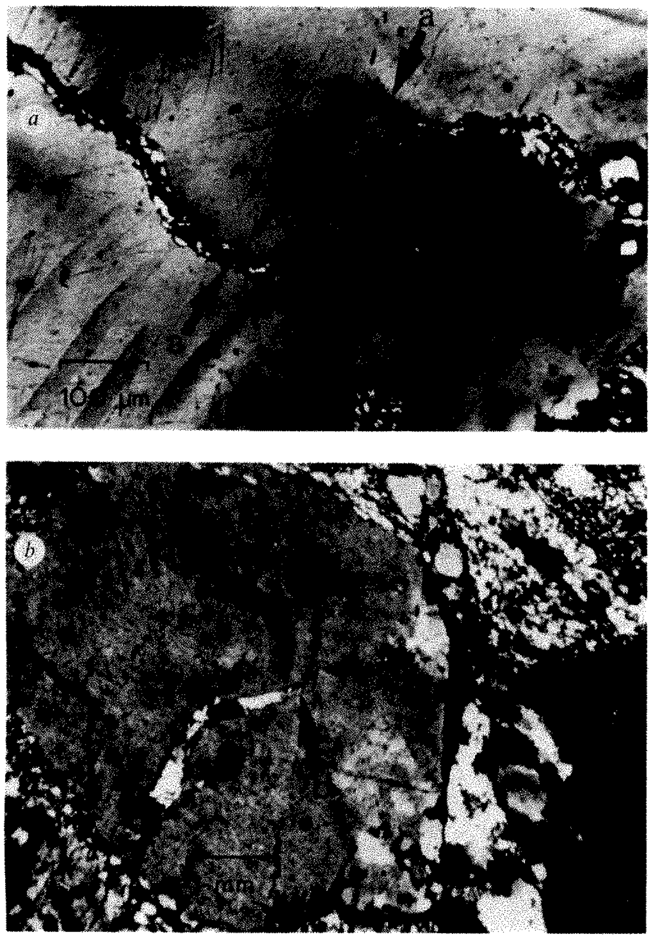

Fig. 1 *a*, Basal plate of biotite, within deformed granodiorite, containing fractures occupied by secondary ilmenite (a), muscovite and biotite. *b*, Phenocryst of orthoclase in a deformed granodiorite containing irregular non-displacive tensile fractures (b) occupied by secondary orthoclase, and/or albite; bounded on right hand margin by linear fracture with displacement.

Localisation of reactions ahead of fracture tips may be a diagnostic criterion for stress corrosion cracking, in contrast to alteration of minerals along fractures by means of the enhanced access of reactants. The reactions accompanying cracking described above do not involve any net hydration, as indicated by the relatively constant proportion of volatiles in rocks at all observed states of deformation, and from considerations of the structural water content of reactants and products in cracks. In addition, the δ^{18}O whole rock and ratio of $Fe^{2+}/\Sigma Fe$, both of which are sensitive to water-rock interaction, maintain constant values at increasing states of strain, implying no significant transport of fluids through the deforming rocks. However, the participation of an aqueous phase (as evidenced by the small quantities of fluids present in inclusions) is probably an important factor in catalysing reactions and the transport of components at fracture tips.

Grains of both orthoclase and plagioclase feldspar exhibit abundant microfractures of two distinct morphologies. First, linear fractures which terminate at grain boundaries, are narrow and involve transverse displacements of up to 3 mm (Fig. 1*b*). Second, irregular fractures which generally terminate within crystals, are relatively wide (20–200 μm), and have little discernible evidence of translation (Fig. 1*b*). The latter type of fractures are occupied by secondary reaction products of the parent grain, and are believed to have propagated by stress corrosion. Towards the boundaries and leading edge of irregular fractures parent grains become free of solid inclusions such as sericite, compared to regions remote from fracturing. During the cracking process sericite appears either to have migrated to the crack boundaries which it locally decorates, or to have reacted to secondary orthoclase in fractures, or to have been removed from the local chemical system. Secondary feldspar within fractures is clear, and contains abundant primary fluid inclusions in the sub-20 μm size range.

Dilatant fractures orientated normal to the local stretching direction are generally occupied by feldspar fibres growing in the direction of extension, bridging the fracture boundaries. In general, fractures are occupied with secondary feldspar of approximately the parent grain composition. However, many oligoclase phenocrysts recrystallise to a more sodic composition with corresponding loss of Ca, accompanied by loss of K as sericite is removed (Table 2). This reaction also proceeds during recrystallisation of oligoclase at grain boundaries[7]. Phenocrysts of orthoclase may have fracture fillings of orthoclase, plagioclase, or both feldspars coexisting, and this is also true for plagioclase phenocrysts (Table 2).

Stress corrosion cracking gives rise to grain size reduction in the rocks described and is probably operative in low to medium temperature environments where crystal plasticity is not generally predominant. However, its overall role in crustal deformation is not known. One possible consequence of this process is enhanced permeability, especially for reactions with a negative ΔV.

We thank Drs S. Aryton and J. Starkey for contributing material from Miéville, Dr T. LaTour for helpful criticisms, and Mr J. Forth for technical assistance.

Optical demonstration of crystalline superstructures in binary mixtures of latex globules

Sei Hachisu & Shigekuni Yoshimura

Institute of Applied Physics, University of Tsukuba,
Sakura Ibaraki 305, Japan

The colloid known as monodisperse latex[1] is an aqueous suspension of a synthetic polymer, the particles of which are ideally spherical and uniform in size (monodisperse). It shows phase transition[2] from a disordered to an ordered state, changing its appearance from milky white to iridescent. This is considered as experimental verification of the transition found by computer calculations[3,4] of concentrated hard core systems. Thus, monodisperse latex is a reliable model for studying the statistical mechanics of concentrated systems. Furthermore, as the particles are visible[5,6] by light microscopy when they are larger than 0.3 μm, we can now directly see what happens during phase transition and related phenomena. Recent work on the structure of gem opals[7] offers an important clue to understanding the statistical properties of binary systems. It showed that in some unusual opals two kinds of silica spheres of different size form a superstructure with long period. The structure must have been formed in a stable dispersion of silica spheres[7] and then been condensed and dehydrated. It should be possible to produce the structure artificially in some colloids and so provide an excellent model of binary systems. We report here that we have succeeded in producing superstructures in mixtures of two monodisperse polystyrene latexes of different particle size and have observed them microscopically[5] in their natural (stably dispersed) state. Several structures were found, including the alloy structures of $NaZn_{13}$ and $CaCu_5$ types, which belong to the so-called size-factor compounds[8].

The survey was made over a wide range of particle–number ratio for many combinations of latexes. For every mixture, the total solid content was adjusted to about 0.1 volume fraction, and their electrolyte (KCl) concentration was maintained at around 10^{-5} mol l^{-1}.

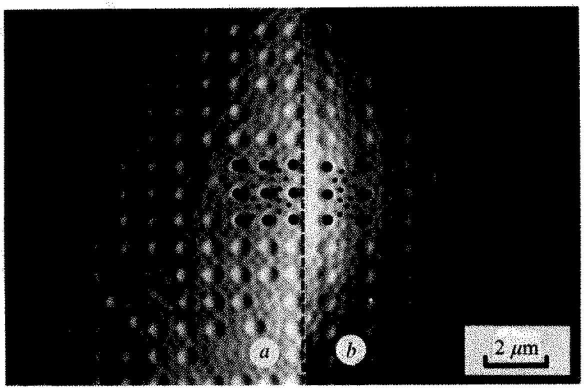

Fig. 1 Photomicrographs of the superstructure in a mixture of 5,500 Å and 2,700 Å latexes taken by light (metallurgical) microscope. Large spheres represent 5,500 Å particles and small ones 2,700 Å particles. Lattice type is simple cubic with respect to 5,500 Å particles. *a* Represents the (100) plane, and *b* the (110) plane. To distinguish the configuration of 2,700 Å particles, a superlattice is drawn. Staggered rhombuses can be seen in the (100) plane and a distorted pentagon in the (110) plane. The 2,700 Å particles were not static; from time to time they underwent a collective motion.

When conditions were optimal, in ten to several tens of hours after placing the cell on the microscope the ordered structures appeared. At this stage, the ordered regions were 'islands' about 50 μm in diameter surrounded by a 'sea' of irregular structure, but within a few days had grown to reach an equilibrium state in which the ordered structures coexisted with the disordered structure. These features were in accord with Sanders' observations on opal specimens[7].

The formation was quite reversible; the structures once formed could be broken by slight mechanical shock and reformed in several hours. The phenomenon resembled a kind of phase separation. The condition necessary for the ordered structures to appear is the basic problem of statistical mechanics of binary systems. It was rather strict, depending on the total solid content, the size ratio, the particle–number ratio and electrolyte concentration, and will not be discussed here. We will describe only two of the various structures discovered.

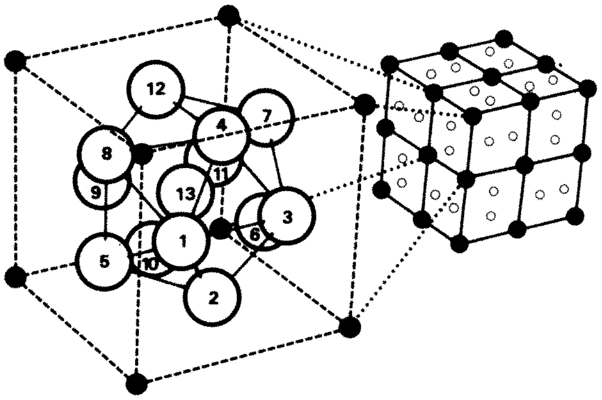

Fig. 2 Superstructure of the AB_{13}-type structure. Small solid circles indicate the position of the 5,500 Å particles and open circles represent the 2,700 Å particles forming a centred icosahedron. Particles 1, 2, 3 and 4 appear under the microscope as a rhombus in the (100) plane. Particles 2, 3, 4, 8 and 5 form a distorted pentagon in the (110) plane. The orientation of the icosahedron changes by 90° between adjacent cells.

Figure 1 shows patterns that appeared in the 5,500–2,700 Å system, the particle–number ratio of which was 1 : 8. These are, respectively, the (100) and (110) net planes of a simple cubic lattice with respect to 5,500 Å particles. The lattice constant was 0.85 μm. By moving the microscope focus upwards (an inverted-type microscope was used), we could find the next net plane. The mode of superposition of successive net planes and the measured spacing between them supported the simple cubic model.

The arrangement of the smaller particles is, however, rather complicated. The (100) plane contains four particles, which seem to be in the form of a rhombus (strictly speaking, it would be a shallow tetrahedron). The (110) plane contains six particles, five of which form a distorted pentagon with one particle at its centre. The centering particle must be situated at the body centre of the simple cubic lattice of 5,500 Å particles. Then, the simple cubic unit cell must contain four small particles in each of its side planes and one at its centre. This leads to the composition AB_{13} for this structure, in agreement with Sanders' opinion (personal communication).

The staggered arrangement of the rhombuses in the (100) plane indicates that the unit cell of the superstructure must be a block consisting of eight of the single cubic cells of 5,500 Å particles. The orientational behaviour of the distorted pentagon in the (110) plane is also interesting. These features are explained by assuming that the structure is as shown in Fig. 2. Note that this is the same, at least in particle configuration, as the structure of intermetallic compounds of $NaZn_{13}$ type[9].

0028-0836/80/020188—02$01.00

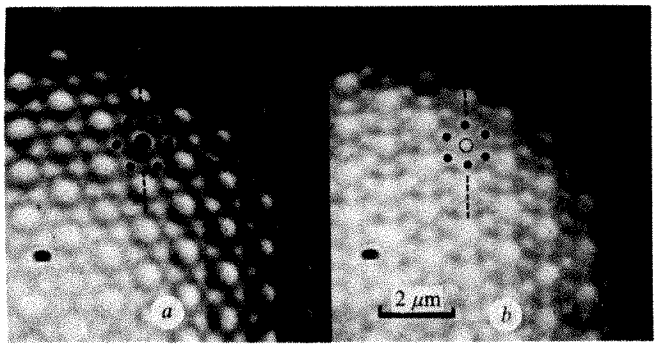

Fig. 3 Patterns observed in a 5,500–3,100 Å particle mixture. *a* Shows the pattern of the first plane, and *b* that of the second plane which lies about 4,000 Å above the first plane. Small particles in the first plane are at the centres of triangles of large particles, whereas those in the second plane lie at the midpoints of the lines connecting the blurred images of the larger particles. This is characteristic of an AB_5-type alloy structure.

Figure 3*a* shows a hexagonally ordered structure which appeared in a 5,500–3,100 Å system, the particle–number ratio of which was 1 : 2. On moving the microscope focus upwards by 0.8 µm, the next plane of the same arrangement appeared. All the particles, large and small, were directly above those in the first plane; no staggering was found. Then, moving the microscope focus down from this plane very carefully, another new plane was found lying between the above-mentioned two planes (see Fig. 3*b*), but in this new plane the smaller particles were arranged in a different way from those in Fig. 3*a*. The larger particles in Fig. 3*b* are out of focus, indicating that they are not in this plane. This new plane seems to consist solely of 3,100 Å particles, for if there were 5,500 Å particles here, they would have to lie between two infocused large particles whose centres are only 0.8 µm apart, which is impossible. Figure 4 shows the particle arrangement in the two planes. The superstructure must be composed of a combination of these two planes. Brief consideration leads to the formula AB_5 as the composition. This again corresponds to the structure of an intermetallic compound, in this case, $CaCu_5$ (ref. 10). This resemblance between the superstructure in latex and those of some alloys is very interesting. These latex superstructures may, therefore, be called 'colloid alloys'.

Because the electrolyte concentration is very low in the present systems ($\sim 10^{-5}$ mol l^{-1}) the colloid interaction between the particles must be repulsive, and in general, repulsive forces work to make the whole system uniform, and do not explain the occurrence of phase separation. Therefore, the mechanism of formation of these structures must be due to some entropy effect[2,3]. This means that in intermetallic compounds of this kind, the stoichiometry is determined by the size ratio of the component atoms; the electrons act only as a cement to hold the atoms together, and this cementing action can be replaced by pressure.

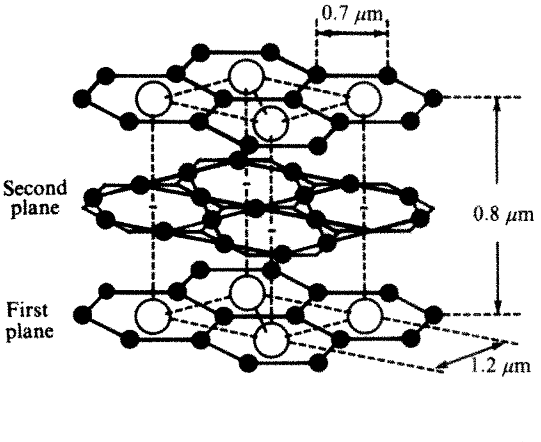

Fig. 4 Illustrative drawing of the AB_5-type structure. The interlayer spacing is exaggerated for convenience. Open and solid circles represent the 5,500 Å and 3,100 Å particles, respectively.

Influence of stratospheric cooling from CO_2 on the ozone layer

I. S. A. Isaksen, E. Hesstvedt

Institute of Geophysics, University of Oslo, Norway

F. Stordal

Norwegian Meteorological Institute, Oslo, Norway

Perturbation of the atmospheric temperature distributio caused by an increased content of CO_2 is a key problem i climate research. The main concern is the increase in temperatures at the Earth's surface due to an increased greenhous effect. A general cooling of the stratosphere is predicted to tak place when CO_2 increases. A direct effect of lower temperature in the stratosphere is a change in the rates of some of th chemical reactions which control the ozone layer. Anthropogenic release of carbon dioxide may therefore lead to change in the ozone layer in the future. The present paper shows tha estimates of the temperature effect on ozone depend markedl on the level of chlorine in the stratosphere, as the catalytic ozon reduction by nitrogen and chlorine reactions respond differentl to changes in temperature.

Model estimates[1–3] predict an increase in the stratospheri ozone content with decreasing temperatures. This would mea that future decreases in stratospheric ozone due to fluorcarbo releases might have considerably fewer environmenta consequences due to an effect opposite to that of CO_2. I particular Groves *et al.*[3] find the effect from increased CO_2 to b significant compared with future chlorofluoromethane (CFM effects. To estimate the effect of reduced temperatures o stratospheric ozone, they used a one-dimensional time-dependent model with temperature feedback included. We have use a similar chemical transport model, with prescribed temperatur profiles, to repeat their calculations of the temperature effect o ozone. Our calculations give smaller changes in total ozone.

The one-dimensional time dependent model is the same a that used by Hessvedt and Isaksen[4], with updated rate constant Groves *et al.*[3] calculate the effect of increased CO_2 on tot ozone in a model which does not include chlorine reaction while our model takes the chlorine chemistry into account. T

0028-0836/80/020189—03$01.00

compare the models from a technical point of view, we calculated the effect of reduced temperatures corresponding to doubled CO_2 content in the atmosphere (600 p.p.m.), neglecting the chlorine chemistry. We also adjusted the rate constants for the more important reactions (the reactions of HO_2 with NO and O_3) in accordance with the values used by Groves *et al.*[3]. The resulting increase in total ozone density agrees well with the increase obtained by Groves *et al.*—5.6% compared with 5.5%. Calculated increase in ozone with height in the stratosphere is also found to be in good agreement in the two models. Thus the smaller increase in ozone obtained in our model is probably a result of a more complete ozone chemistry obtained through consideration of chlorine reactions. This point is discussed further below. Groves and Tuck[5] have recently shown that the temperature effect also becomes smaller when chlorine reactions are included in their model.

Future effects of CO_2 on ozone are obtained by two sets of calculations. Chlorine variations are the same in the two sets of calculations, determined by the release of CFMs, while we use two different temperature profiles. In the first set of calculations a standard temperature profile is used. In the second a different profile is used in the stratosphere, corresponding to doubling (600 p.p.m.) of CO_2 in the atmosphere. The difference in total ozone between the two sets of calculations at a certain year should therefore give the effect of the adopted temperature change for a chlorine content corresponding to that year. In which year this will take place, will depend on the future release rates of CO_2, Freon 11 and Freon 12 (F-11 and F-12). The temperature profile we adopt, corresponding to doubled CO_2 in the atmosphere, is the same as that calculated and used by Groves *et al.*[3]. It gives a temperature reduction of 4 °C at 25 km, 6 °C at 30 km, 10 °C at 40 km, and 13 °C at 50 km. These values refer to summer conditions. During the winter reductions are somewhat lower. The numbers are in good agreement with stratospheric cooling obtained by Manabe and Wetherald[6].

In the present model increase in the stratospheric chlorine content is calculated from a yearly release of F-11 and F-12 up to 1977 [7] which is approximately 85–90% of the production the same year. After 1977 constant release rates, equal to the 1977 production are adopted. Table 1 gives the calculated increase in total ozone density (in per cent) which would result from a doubling of the CO_2 in different years. As the change in ozone for each year is calculated with the same amount of chlorine present, the value in Table 1 gives the effect of temperature alone on ozone, at that certain level of chlorine.

The value for year 1955 refers to the chlorine content in the atmosphere before it was affected by release of F-11 and F-12. The source for chlorine before 1955 is assumed to be release of CH_3Cl and CCl_4. Both these compounds are assumed to be of natural origin and therefore to have constant release rates. For the years after 1955 Table 1 gives the amount of ClX, which is calculated to be present in the stratosphere above 30 km as a function of time. The temperature effect is seen to become less pronounced the more chlorine there is in the stratosphere. With the amount of chlorine estimated to be in the stratosphere in year 2040, a doubling of the CO_2 in the atmosphere leads to an increase in total ozone of 2.8%, slightly more than half the increase we obtain for a negligible chlorine content.

Table 1 Calculated increase in total ozone versus time resulting from the temperature changes given by a doubling of the CO_2 content in the atmosphere at various chlorine concentrations

Year		1955	2000	2020	2040
ClX (parts per 10^9)	0	1.0	2.6	3.5	4.4
$\Delta O_3/O_3$ (%)	5.1	4.3	3.3	3.0	2.8

The ClX ($Cl+ClO+HCl+ClNO_2$) mixing ratios are given for heights above 30 km, and are calculated in the model assuming a constant release rate of CFM at the 1977 level. The increases shown are for summer conditions.

Table 2 The ozone loss at various heights in the stratosphere in % of total loss at each height

	Chemical cycles			
Height (km)	Oxygen*	Hydrogen†	Nitrogen‡	Chlorine§
45	16.1	24.9	9.5	49.5
40	8.7	8.3	16.3	66.7
35	7.3	5.6	23.8	63.2
30	8.1	10.4	22.5	59.0
25	6.7	29.8	12.9	50.6
20	3.1	74.6	5.8	16.5

The loss in each group is obtained from the following reactions:
* Oxygen: $O+O_3 \rightarrow 2O_2$
† Hydrogen: $HO_2+O \rightarrow OH+O_2$ and $HO_2+O_3 \rightarrow OH+2O_2$
‡ Nitrogen: $NO_2+O \rightarrow NO+O_2$
§ Chlorine: $ClO+O \rightarrow Cl+O_2$
The values refer to the estimated stratosphere chlorine content for the year 2040, and are for the summer season.

We find this marked reduction of the effect of temperature changes, when the chlorine content is increased, to result from the different ways nitrogen and chlorine reactions respond to temperature changes. In the nitrogen cycle the ozone loss is proportional to the concentrations of NO_2. Reduced temperatures reduce the production of NO_2 from NO:

$$NO+O_3 \rightarrow NO_2+O_2 \qquad k_1=2.1\times10^{-12}\,e^{-1450/T} \qquad (1)$$

thereby lowering the equilibrium concentrations of NO_2. This makes the nitrogen cycle less effective, with the result of increased concentrations of ozone.

In the chlorine cycle where there is chemical equilibrium between Cl, ClO, and HCl, a change in the temperature profile first of all affects the reaction:

$$Cl+CH_4 \rightarrow HCl+CH_3 \qquad k_2=7.3\times10^{-12}\,e^{-1269/T} \qquad (2)$$

This reaction converts active chlorine, Cl and ClO, to HCl which is inactive with respect to ozone destruction. A temperature reduction in the stratosphere will therefore increase the ozone destruction by chlorine reactions. The calculations show that a temperature reduction of approximately 10 K at 40 km reduces the NO_2 densities, and thereby the ozone destruction through the nitrogen cycle by approximately 10%. It increases the ClO densities, and thereby the ozone destruction through the chlorine cycle by approximately 6%. Similar changes in NO_2 and ClO are found at other heights. Other species are found to be little affected by changes in temperature.

When the chlorine chemistry is considered in the model, the importance of the nitrogen cycle for the ozone distribution is markedly reduced. This will particularly be true when high chlorine build up takes place during the next century as we have predicted in Table 1. This is clearly illustrated in Table 2 where the loss (in relative units) due to the different chemical cycles is given. The numbers refer to the year 2040. In the region between 30 and 40 km where the temperature effect from a CO_2 increase has the largest impact on total ozone, the catalytic chlorine reactions are responsible for approximately 60% of the ozone destruction. It is therefore not surprising that the temperature effect on ozone is found to vary considerably with varying chlorine content in the stratosphere. A consequence of this is that comparisons of future effects of CO_2 and CFM also must take into account how long it takes for CO_2 to double its atmospheric concentrations, and how accurate the adopted release rates of CFM are. In these comparisons we have assumed that CO_2 will reach 600 p.p.m. around year 2040. Unfortunately this assumption, and also the assumption of a future release rate of CFM on the 1977 level are both highly uncertain.

In order to compare the effect of future increase in atmospheric CO_2 with the effect of increased CFM levels, estimated reductions of total ozone due to constant future CFM release on the 1977 level are given in Table 3. The calculations show that there will be a marked decrease in ozone well into the next

Table 3 Calculated changes in total ozone concentrations versus time due to the release of CFMs (F-11 and F-12)

Year	1978	2000	2020	2040	$\rightarrow\infty$
$\Delta O_3/O_3$ (%)	−1.9	−7.4	−11.1	−13.9	−23.4

Release rates up to 1977 are taken from ref. 7. A constant release rate correponding to the production in 1977 is adopted for the years after. Effects from changes in stratospheric temperatures are neglected. The changes shown are for the summer season.

century. The reduction due to CFM release in year 2040, which is of special interest when comparisons with the CO_2 effect is made, is approximately 14%. Compared with the 2.8% increase in total ozone from a doubling of CO_2 we obtained above, we find the temperature effect due to increased CO_2 to be only an adjustment of the CFM effect. Note, however, that the above values are likely to represent overestimates of the CFM effect as we have not considered any feedback from reduced O_3 in the stratosphere to the temperature profile. However, estimates of this effect[8] indicate that it leads to a small change in the CFM reduction of ozone. The calculations of Groves and Tuck[5] show considerably smaller future reductions in total ozone when the combined effect of CO_2 and CFM is considered, than those obtained in our calculations.

Nitrogen fertiliser and stratospheric ozone: latitudinal effects

R. C. Whitten*, W. J. Borucki*, L. A. Capone†, C. A. Riegel† & R. P. Turco‡

* Ames Research Center, NASA, Moffett Field, California 94035
† San Jose State University, San Jose, California 95192
‡ R & D Associates, Marina del Rey, California 90291

Substantial increases in atmospheric nitrous oxide (N_2O) resulting from increased use of nitrogen fertilisers might cause large (to 10%; ref. 1) and unacceptable decreases in the stratospheric ozone content[1–3]. Such ozone decreases would be caused by catalytic reaction cycles involving odd-nitrogen ($NO_x \equiv NO + NO_2$) which is formed by N_2O decomposition in the upper stratosphere[1]. However, Turco *et al.*[4], using a background chlorine level of 2 p.p.b.v. (parts per billion by volume), show that if the recently measured values of the reactions in Table 1 are used, a 50% increase in N_2O would lead to a 2.7% increase in the stratospheric column density, although the ozone content above 30 km would be reduced by > 5%; they also estimated (unpublished data) that the change in the ozone column density caused by doubling the N_2O abundance would be very close to zero (within about 0.1%). Here we extend these calculations of N_2O/ozone effects to two dimensions, thereby delineating the latitudinal dependence expected for such ozone perturbations; we also discuss the effects of changes in stratospheric chlorine levels ($Cl_x \equiv Cl + ClO + HCl$) on predicted ozone changes.

The two-dimensional model used in this study extends from the surface to 60 km altitude and from latitude 80° N to 80° S with 2.5 km vertical grid and 5° latitudinal grid. About 35 constituents in the oxygen–nitrogen–hydrogen–chlorine–carbon families are included. Transport is simulated by advection and eddy diffusion. Detailed discussions of the model are given elsewhere[7,8].

We have made model calculations that simulate a doubling of atmospheric N_2O for two possible levels of stratospheric chlorine content, 1.4 p.p.b.v. and 2.1 p.p.b.v., at 60 km altitude. The corresponding predicted changes in ozone abundances are shown in Fig. 1 as a function of altitude and latitude. The most notable feature of these profiles is the substantial ozone increase predicted for the lower stratosphere (up to 10% below 20 km at high latitudes, and up to 15% below 27 km at low latitudes). The ozone gains are caused principally by the interference by enhanced NO_x concentration in the HO_x reaction cycle that consumes ozone; that is, through interference caused by the coupling reaction (see Table 1)

$$NO + HO_2 \rightarrow NO_2 + OH \qquad (1)$$

This occurs via two major mechanisms. One is accelerated HO_x recombination through reactions involving nitric acid

$$(OH + NO_2 \xrightarrow{M} HNO_3;\ OH + HNO_3 \rightarrow H_2O + NO_3).$$

The second suppresses HO_x catalysis of ozone by direct short circuiting of the reaction

$$HO_2 + O_3 \rightarrow OH + 2O_2 \qquad (2)$$

by reaction (1) (see Table 1). Eventually, as NO_x is increased beyond some level, enough of the OH is taken up by nitric acid and destroyed by the reaction $OH + HNO_3$ that it decreases as NO_x is increased. Our computations, in fact, show that OH may be reduced by nearly 10^6 molecules cm^{-3} (by about 25%) for N_2O doubling, especially at mid-latitudes and high latitudes. Reductions in OH have, of course, consequences for the lifetimes of other stratospheric constituents, including many hydrocarbons and halocarbons.

Figure 2 shows the predicted latitudinal variation of the relative (per cent) ozone column density change for two levels of stratospheric chlorine (1.4 p.p.b.v. and 2.1 p.p.b.v.). The important features to be noted here are the minima that may occur at low latitudes, and the pronounced influence of the ambient stratospheric chlorine level. The low latitude minima would occur partly because of stratospheric transport, which

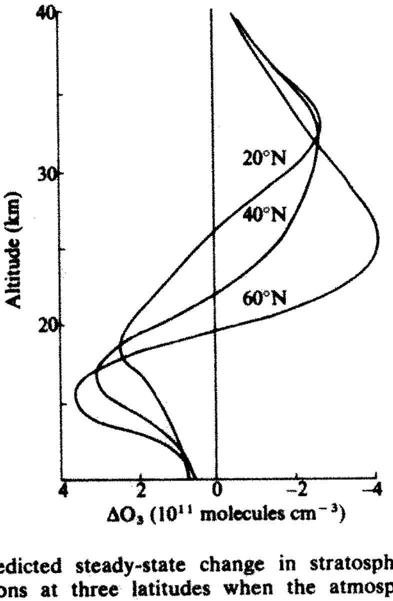

Fig. 1 Predicted steady-state change in stratospheric ozone concentrations at three latitudes when the atmospheric N_2O abundance is doubled. The level of stratospheric chlorine is 2.1 p.p.b.v.

0028–0836/80/020191—02$01.00

Table 1 Some key reactions

Reaction	Rate coefficient*	Ref.
(1) $NO+HO_2 \rightarrow NO_2+OH$	8×10^{-12}	5
(2) $HO_2+O_3 \rightarrow OH+2O_2$	$1.4\times10^{-14}\exp\left(\frac{580}{-T}\right)$	6

T is the absolute temperature in degrees Kelvin.

moves relatively inert substances (tracers), such as ozone and total odd-nitrogen, from low to high latitudes[9]; as a result, NO_x increases at higher latitudes. On the other hand, increases in the background level of chlorine are predicted to cause less ozone destruction due to increase of N_2O, mainly because of the reaction

$$NO+ClO \rightarrow NO_2+Cl \tag{3}$$

and to a lesser extent through the formation of chlorine nitrate ($ClONO_2$). As NO_x is increased, this strong Cl_x–NO_x coupling reaction significantly slows the rate of ozone catalysis by ambient chlorine. In other words, the addition of NO_x can render the ambient chlorine catalytic cycle less effective through reaction (3) and can, if the chlorine concentration is high enough, result in an ozone increase. Hence the complex interplay among the NO_x, HO_x, and Cl_x reaction cycles (also discussed in ref. 10) at first leads to a net ozone increase as N_2O burdens are increased, which later 'saturates' and becomes a net ozone decrease. This effect was predicted by Turco *et al.*[4] for aircraft injections of NO_x into the stratosphere. The present calculations show that the saturation point is indeed very sensitive to the ambient chlorine level, and is not uniform over the globe. Note also that this prediction is highly sensitive to other model parameters, including the ambient water vapour concentration and the rates of several key reaction processes such as reactions (1) and (2). Qualitative estimates of the rates of odd-oxygen (ozone) consumption for the key catalytic reaction steps are presented in Fig. 1 of ref. 4. The global average ozone changes shown in Fig. 2 are roughly consistent with those obtained with our one-dimensional model[4]. Note that the hemispherical asymmetry in Fig. 2 is a consequence of the asymmetry in eddy transport required for matching observed ozone abundances by model predictions. The small differences between the two models are due mainly to differences in effective vertical transport. That is, for the high chlorine case, we obtain an annually and globally averaged ozone change of about −0.5%; the corresponding prediction with the one-dimensional model is zero change. The difference is due to a somewhat different mean vertical transport rate between the two models.

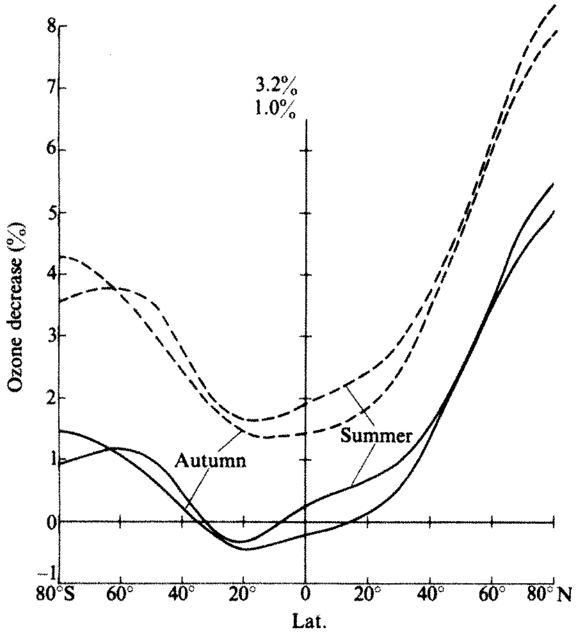

Fig. 2 Predicted latitude dependence of the change in the ozone column density for the summer and autumn seasons and for two levels of stratospheric chlorine: $Cl_x = 1.4$ (dashed line) and 2.1 p.p.b.v. (solid line).

The cycle of atmospheric nitrous oxide is not well understood. A major controversy centres on the possibility of a large unidentified tropospheric sink for N_2O. If the magnitude of that sink is as large as has been suggested by Hahn[11], it is unlikely that the abundance of atmospheric N_2O will double in the next 50 years. Inasmuch as stratospheric levels of chlorine are expected to exceed about 2 p.p.b.v. in future decades, our calculations suggest that global ozone reductions due to large N_2O increases could be quite small, and that they should be most pronounced at high latitudes; at low latitudes, ozone column increases are actually likely to occur. Thus, because the atmospheric lifeline of N_2O is probably not much larger than 10 years, we apparently have the time to carry out an extended and detailed scientific analysis of the global N_2O budget before critical decisions concerning the regulation of nitrogen fertilisers will be necessary.

Ethylene evolution by thrips-infested cowpea provides a basis for thrips resistance screening with ethephon sprays

H. C. Wien* **& C. Roesingh†**

International Institute of Tropical Agriculture, PMB 5320,
Ibadan, Nigeria

Pests are major constraints to increased cowpea production in tropical subsistence agriculture where cash inputs are small. Breeding for pest resistance is therefore the major component of pest management strategies for crop improvement. Of paramount economic importance among these pests are flower thrips [*Megalurothrips sjostedti* (Tryb.)] which may cause abscission of flower buds, flowers and peduncles, leading to seed yield losses of up to 100% (refs 1, 2). It has been difficult to use available sources of moderate thrips resistance in a breeding programme because of thrips variation in time and space in field screening[3]. This paper reports that ethylene is produced when thrips infest cowpea peduncles. We have used this fact to develop a screening technique using the synthetic growth regulator ethephon (2-chloroethylphosphonic acid), which when sprayed on the plant is translocated to actively-growing tissue, where it breaks down to form ethylene[4–6]. Cultivars susceptible to abscission caused by thrips also show increased abscission with ethephon treatment. The technique may be useful in identifying sources of resistance to other abscission-causing agents.

Evidence that thrips damage can lead to ethylene production was obtained when pot-grown plants of two cowpea cultivars (*Vigna unguiculata* L. Walp.), raised in insect-free conditions, were transferred to a thrips-infested cowpea field and ethylene evolution of the peduncles was measured. Half the plants were treated with the systemic insecticide monocrotophos 1 day before transfer to the field. The insecticide-treated plants remained free of thrips, while unsprayed plants showed an average of three adult thrips and six nymphs per peduncle 4 days after field transfer. At that time, when flower bud abscission of the unsprayed plants was just beginning, three peduncles were removed from six plants in each treatment and incubated at 23 °C in 10-ml plastic syringes under 0.75 bar suction tension. To absorb CO_2 given off in respiration, 0.2 g solid KOH was placed in a perforated plastic vial in each syringe. After 24 h incubation, a 0.5-ml gas sample from the syringe was injected in a gas chromatograph for determination of the presence of ethylene[7]. Thrips-infested peduncles produced 640 nmol ethylene per g fresh weight per 24 h and the controls produced 152 nmol. The differences are significant at the 1% level. There was no difference between the two cultivars.

Therefore, it seems that thrips infestation leads to ethylene evolution. As no attempt was made to remove the thrips from infested peduncles before incubation, the source of the ethylene still remains to be determined. The most likely source would be ethylene evolved by the outer cell layers of the flower buds and peduncles that had been injured by the thrips[8,9]. Ethylene could also be produced by the plants as a result of interactions with chemicals secreted by the insects, as occurs in cotton[10].

Can applications of the ethylene-producing chemical ethephon simulate thrips damage, and identify cultivars resistant to thrips? To answer these questions two field experiments, comparing flower bud and peduncle abscission of 30 cowpea lines were planted in first and second rains at IITA, Ibadan. Plots consisted of single rows 1 m apart and 3 m long, replicated four times. Both experiments were sprayed weekly with insecticides starting at 2 weeks after sowing. Applications of 0, 200 or 400 p.p.m. ethephon in water containing 0.5% (v/v) of a wetting agent formed the main plots, with cultivars as subplots in the split plot experiments. In experiment 1, a single ethephon spray was applied at about 1 week before anthesis of a particular cultivar. At this stage, the oldest peduncles were about 1 cm long. In experiment 2, all cultivars were sprayed 34, 39 and 47 days after sowing with 0, 200 or 400 p.p.m. ethephon, to ensure that each cultivar received at least one spray during the period of maximum sensitivity to abscission. In both experiments the five lowest peduncles on the main stem of three plants per plot were examined for peduncle or flower bud abscission 2–4 days after the controls started flowering. Only the lowest two buds per peduncle were considered in rating flower bud abscission. The number of plants flowering was counted on each plot at 2–3 day intervals.

The same 30 cultivars were field tested for thrips resistance in four replications in late second rains without insecticide protection (experiment 3). Flower thrips infestation was heavy and completely prevented flowering of some cultivars. After 50 days, thrips susceptibility was measured by counting the number of abscised peduncles on the first five nodes of the main stem of three plants per plot.

In experiments 1 and 2 ethephon sprays resulted in increased peduncle abscission and reduced budset in all cultivars, with thrips-susceptible cultivars being most severely affected (Table 1). Thrips-resistant cultivars showed less damage than susceptible lines with 200 and 400 p.p.m. ethephon (spray treatment × cultivar interaction was significant at the 1% level). There was no evidence of enhanced fruitset at concentrations of 250–500 p.p.m. as reported for *Phaseolus vulgaris*[11].

The correlation between per cent peduncle abscission due to ethephon and that due to thrips was 0.75 and 0.62 for experiments 1 and 2, respectively (Fig. 1). In both experiments, five cultivars showed good levels of resistance to ethephon and to thrips, indicating that selection of plants with low main stem peduncle abscission after sprays of 400 p.p.m. ethephon can identify individuals with thrips resistance. Five other cultivars showed low incidence of peduncle abscission due to thrips after one spray of 400 p.p.m. ethephon, but less tolerance to repeated applications of the chemical. Such cultivars may be less resistant to higher thrips populations than occurred in experiment 3.

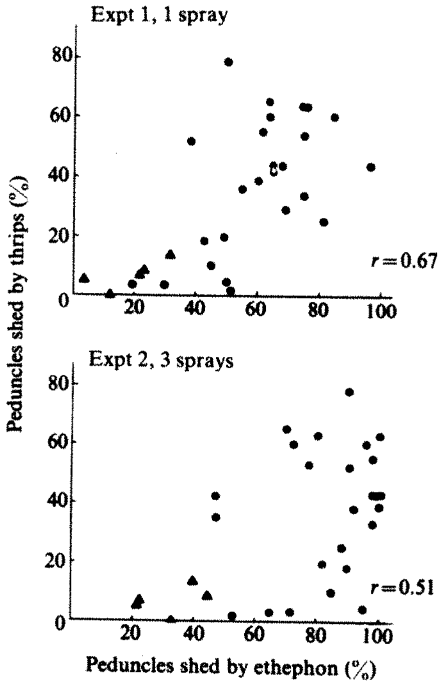

Fig. 1 The relationship of peduncle abscission caused by thrips and by 400 p.p.m. ethephon for 30 cowpea lines grown in two field experiments. Points marked by a triangle represent lines that have shown consistent thrips resistance in other experiments.

It seems clear that ethephon sprays can assist in identifying cowpea lines which possess flower thrips resistance. The sprays can be applied uniformly, and as resistance is built up through intercrosses of different resistant parents, the dosage level could be increased to simulate heavier thrips pressure. The thrips resistance of such material would require verification, for in large plantings of a resistant cultivar, thrips levels may build up sufficiently to cause damage.

The use of ethephon as a screening tool for abscission resistance could have important implications for other crop improvement programmes. Various insect pests are known to cause abscission of young reproductive structures in cotton[11-13] and plum[14], while drought, high temperatures and shade may cause similar damage in edible legumes[7,15,16]. Increases in evolution of ethylene may result from insect damage[11], shading, drought[17,18] or plant disease[19].

Thus the abscission response of cultivars to different levels of applied ethephon might identify lines with better tolerance to such pests and stress conditions. Although some authors have pointed out cultivar differences with regard to abscission of reproductive structures[20,21] the systematic screening for cultivars less susceptible to abscission has to our knowledge not been previously reported and seems a promising way of overcoming the problems of abscission-causing insect pests and physical factors.

Is prostacyclin a physiologically important circulating anti-platelet agent?

Michael L. Steer*, D. Euan MacIntyre*†, L. Levine‡ & Edwin W. Salzman*

* Department of Surgery, Beth Israel Hospital and Harvard Medical School, Boston, Massachusetts 02215
‡ Department of Biochemistry, Brandeis University, Waltham, Massachusetts 02154

Prostacyclin (PGI_2) is a naturally occurring arachidonic acid metabolite which causes relaxation of vascular smooth muscle[1] and is the most potent inhibitor of platelet aggregation known[2]. The anti-aggregatory effects of PGI_2 result from its ability to stimulate platelet adenylate cyclase and elevate platelet cyclic AMP levels[3,4]. The possibility that PGI_2 is a circulating hormone that acts to inhibit platelet aggregation *in vivo* was first suggested by Gryglewski *et al.*[5] and Moncada *et al.*[6]. In their studies using heparinised rabbits and cats, exogenous PGI_2 caused a decrease in superfused *ex vivo* tendon weight, and this effect was inhibited by infusion of antiserum directed against a stable PGI_2 analogue (5,6-dihydro-PGI_2). Tendon weight gain occurred in the absence of exogenous PGI_2 and was enhanced by infusion of PGI_2-binding antibodies, an effect that was more pronounced in arterial than in venous blood. In contrast, Smith and coworkers[7] observed that their PGI_2-binding antibodies (antiserum directed against 6-keto-$PGF_{1\alpha}$) suppressed the vasodepressor effects of exogenous PGI_2 infused into cats but did not alter blood pressure in the absence of exogenous PGI_2. They concluded that PGI_2 is not a circulating vasodepressor hormone. The present studies were designed to examine the physiological role, if any, of circulating PGI_2 in the regulation of human platelet function. Here, we report the results of experiments dealing with the effects of PGI_2 and antibodies directed against 5,6-dihydro-PGI_2 on human platelet function and cyclic AMP levels. These studies indicate that, in humans, PGI_2 is not a physiologically important circulating inhibitor of platelet aggregation.

Antibodies which neutralise the effects of PGI_2 were raised in rabbits using the stable PGI_2 analogue $6\alpha,H$-5,6-dihydro-PGI_2 (PGI_1) as the hapten. The preparation of these antibodies and their detailed serological specificity has been reported previously[8]. The γ-globulin fractions of the immune plasma (anti-PGI_1) and control rabbit plasmas were purified by precipitation with 40% ammonium sulphate. The insoluble proteins were dissolved in 0.14 M NaCl and 0.01 M Tris (*p*H 7.4) containing 0.1% gelatin and dialysed against this buffer. The final γ-globulin concentration was equivalent to that in the unextracted plasma. Platelet aggregation was quantified by measuring the maximal slope of aggregation after addition of ADP[9]. Platelet cyclic AMP was measured using a commercially available radioimmunoassay kit after acetylation of the unlabelled cyclic AMP[10]. In the cyclic AMP experiments, platelets were separated from plasma by centrifugation through a layer of silicone oil into trichloroacetic acid (TCA). This method, which results in >90% platelet recovery in the TCA layer and separates platelets from plasma in less than 1 min, will be described in detail elsewhere. (M.L.S., in preparation).

Addition of PGI_2 (1 nM) to platelet-rich plasma (PRP) more than doubled the platelet level of cyclic AMP at the first time measured (2.5 min) (Fig. 1). Platelet aggregation induced by

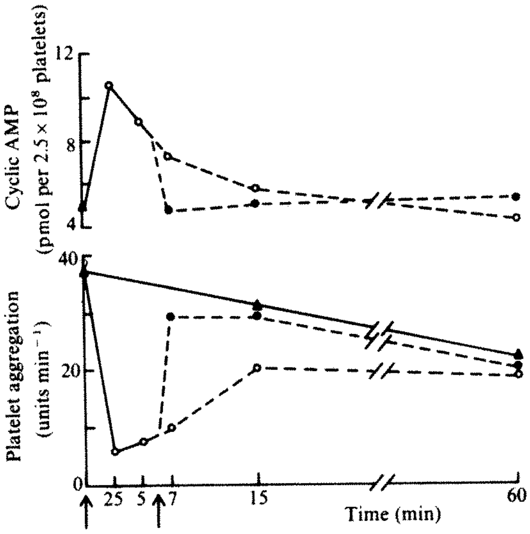

Fig. 1 Typical experiment showing the effect of PGI_2 and antibodies that bind PGI_2 on platelet cyclic AMP levels and ADP-induced platelet aggregation. PGI_2 (1 nM) was added to the PRP at zero time (1st arrow) and 50 μl ml^{-1} of either γ-globulin from an immune rabbit (anti-PGI_1) or γ-globulin from normal plasma was added at 6 min (2nd arrow). Cyclic AMP and platelet aggregation were measured as described in the text. Values represent the mean of duplicate determinations which differed by less than ±10%. ●, Anti-PGI_1; ○, normal plasma; ▲, no addition.

The PRP was separated from whole blood by high-speed centrifugation. PRP preparation was completed within 2.5 min of blood collection, and 50 µl ml^{-1} PRP of either immune or control γ-globulin was added immediately thereafter. This amount of immune γ-globulin had previously been found to reverse the anti-aggregatory effects of 3 nM exogenous PGI_2. Aggregation, induced by 2 µM ADP, was measured 30 s, 2.5 min and 7.5 min later (that is, 3, 5, and 10 min after blood collection). Results represent mean ±s.d. of duplicate measurements from either 7 (arterial) or 11 (venous) separate experiments using different donors, none of whom had ingested aspririn-containing drugs during the 2-week period before testing. None of the blood samples contained heparin. The slopes of aggregation at 5 min and 10 min with or without antibodies were compared with the comparable values at 3 min. The statistical significance of differences was evaluated using the *t*-test for paired data. Symbols indicate $^*P<0.05$ or $^\dagger P<0.01$ in this comparison. The 5- and 10-min slopes of aggregation were significantly greater than that at 3 min, but there was no difference between controls and samples containing antibodies in this regard.

ADP (2 µM) was almost totally inhibited at this time. Over the next hour, platelet cyclic AMP levels gradually fell to the original level, while the rate of ADP-induced aggregation rose to the control level. Addition of anti-PGI_1 antibodies 6 min after PGI_2 accelerated the fall in cyclic AMP level and the rise in the rate of ADP-induced aggregation, both of which approximated the initial values within 1 min of addition of the antibody. In contrast, addition of the γ-globulin fraction of plasma from a non-immune rabbit had no effect. Addition to control PRP of immune γ-globulin alone, or of PGI_2 previously incubated with these antibodies, did not alter platelet cyclic AMP levels or ADP-induced aggregation. Thus, the anti-PGI_1 antibodies rapidly reverse the anti-aggregatory effects of exogenous PGI_2.

To investigate whether the sensitivity of platelets to PGI_2 differed in PRP and in whole blood, concentration–response curves for inhibition of ADP-induced aggregation were obtained by addition of exogenous PGI_2 to PRP directly and to whole blood before rapid preparation of PRP. The curves in PRP and in whole blood were virtually identical, and the threshold concentration for inhibition of aggregation was 0.1 nM PGI_2 in both cases. Addition of anti-PGI_2 antibodies to whole blood 15 s after the addition of exogenous PGI_2 (0.1–1 nM) negated the inhibitory effects on platelet aggregation.

If PGI_2 is a physiologically important circulating inhibitor of platelet aggregation, reduction in PGI_2 levels should enhance aggregation. PGI_2 is normally degraded in the circulation with a half-time of 3–5 min (ref. 11), although in citrated plasma the half-time is prolonged to 25–30 min (D.E.M. and E.W.S., unpublished). Previous reports have demonstrated that platelet reactivity *in vitro* increases with time after removal of blood from the vascular system[12,13]. This phenomenon might be explained by time-dependent degradation of PGI_2. We have also found that the rate of ADP-induced aggregation increases with time after rapid preparation of PRP followed by incubation at 37 °C (Table 1). However, immediate addition of anti-PGI_1 antibodies to PRP prepared within 3 min of venous or arterial puncture did not enhance the rate of ADP-induced aggregation at that time or alter the increase in aggregation over the next 10 min. The PGI_2-binding antibodies failed to enhance aggregation in either arterial or venous blood (Table 1).

The present studies demonstrate that: (1) the plasma or blood concentration of PGI_2 required for inhibition of ADP-induced aggregation is ≥0.1 nM; (2) inactivation of PGI_2 by addition of PGI_2-binding antibodies to PRP or to whole blood rapidly (<1 min) reverses the effects of exogenous PGI_2 on platelet aggregation and platelet cyclic AMP; (3) addition of PGI_2-binding antibodies to PRP shortly (<3 min) after either arterial or venous blood collection does not alter platelet aggregation.

If PGI_2 were a physiologically important circulating inhibitor of platelet aggregation in humans, addition of antibodies that neutralise PGI_2 should have enhanced aggregation in these conditions. We conclude that the circulating concentration of PGI_2 in humans is below that required for inhibition of aggregation (<0.1 nM) and that PGI_2 is not a circulating anti-platelet agent in normal conditions in humans. The time-dependent increase in platelet responsiveness after blood collection is therefore not due to degradation of circulating PGI_2.

We thank Dr J. E. Pike, Upjohn, for the gift of PGI_2. This work was supported by NIH grants HL 20956, HL 11414 and HL 25066. Prostacyclin inhibits mobilisation of fibrinogen-binding sites on human ADP- and thrombin-treated platelets

Jack Hawiger, Spencer Parkinson & Sheila Timmons

Prostacyclin (prostaglandin I_2, PGI_2), produced by the blood vessel wall is the most potent known inhibitor of platelet aggregation induced by such stimuli as ADP and thrombin[1]. It binds to a specific platelet receptor[2] and activates adenylate cyclase, raising the cyclic AMP level in platelets[3,4]. This property can be important because platelets participate in several significant interactions. For example, the interaction with fibrinogen or fibrin contributes to the formation of the haemostatic plug[5]. Intact plasma fibrinogen is required for the aggregation of platelets induced by ADP[6], and endogenous platelet fibrinogen influences thrombin-induced aggregation[7]. We have therefore studied the effect of prostacyclin on the interaction of fibrinogen with human platelets. We now report that prostacyclin inhibits the mobilisation of specific binding sites ('receptors') for fibrinogen on human platelets and that this effect parallels the inhibition of ADP- or thrombin-induced aggregation. The inhibitory effect of prostacyclin may limit the extent of platelet–fibrinogen interaction *in vivo* and in extracorporeal circulation.

We isolated platelets from human blood and separated them from plasma proteins by stepwise albumin gradient centrifugation and Sepharose 2B gel filtration as before[8]. All experiments were performed with platelets suspended in HEPES buffer, *p*H 7.35, containing 0.1% dextrose and 0.35% albumin. Aggregation was measured photometrically in a Payton (Buffalo, New York) dual channel aggregometer according to Born's method[9]. Human plasma fibrinogen (Kabi) was prepared and labelled with ^{125}I as before[10]. This preparation was 95% clottable with thrombin. Solutions of PGI$_2$, 6-keto PGF$_{1\alpha}$ and PGD$_2$ were prepared in cold Tris-HCl buffer, *p*H 9.37, immediately before use.

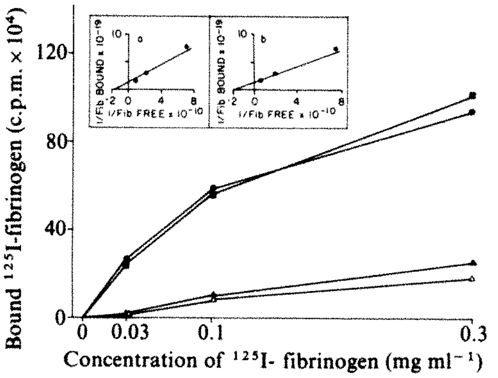

Fig. 1 Binding of ^{125}I-labelled human fibrinogen to platelets exposed to: ■, 4.5 μM ADP; ●, thrombin (0.05 U ml^{-1}) followed by hirudin (0.1 U ml^{-1}); ▲, buffer; △, thrombin or ADP and a 20-fold excess of unlabelled fibrinogen. Each incubation included 1 × 10^8 platelets and the specified amounts of fibrinogen (4.3 × 10^4 c.p.m. μg^{-1}) in 0.5 ml of HEPES buffer, *p*H 7.35, containing 0.1% dextrose and 0.35% albumin. The insets contain double reciprocal plots of binding data for platelets stimulated by ADP and thrombin, respectively. Specific binding was calculated after subtracting values of 'nonspecific' binding in the presence of an excess of unlabelled fibrinogen.

Binding of fibrinogen to platelets was achieved in 0.5-ml reaction mixtures containing 1 × 10^8 platelets with 50 μl of ADP or thrombin preceded or followed by 50 μl of ^{125}I-fibrinogen. To examine the effect of prostaglandins, platelet suspensions were pre-incubated for 3 min with 50 μl of prostaglandin or buffer before the addition of the other agents. Incubation was at room temperature (22 °C) in polypropylene tubes (12 × 75) without stirring. After 15 min the mixture was centrifuged through a 9 : 1 (v/v) mixture of dibutylphthalate and Apiezon oil C (ref. 11). The supernatant was sampled for free radioactivity, and bound radioactivity was measured in the platelet pellet cut off together with the tip of the tube after rapid freezing of its contents in a mixture of dry ice and acetone.

Before examining the effect of prostacyclin on the interaction of ^{125}I-fibrinogen with human platelets, it was necessary to establish the basic characteristics of binding of ^{125}I-fibrinogen to human platelets. Intact, resting platelets bound very little ^{125}I-fibrinogen (Fig. 1). After stimulation with 4.5 μM ADP, there was a four- to fivefold increase in the amount of ^{125}I-fibrinogen bound. Binding to platelets stimulated with ADP approached saturation at 300 μg of ^{125}I-fibrinogen, and equilibrium binding was achieved within 5 min. Approximately 70% of the labelled fibrinogen could be displaced by a 20-fold excess of unlabelled fibrinogen, suggesting that binding was specific. Moreover, adenosine, AMP and ATP in equimolar concentrations did not increase the binding of ^{125}I-fibrinogen to platelets (not shown). The amount of ^{125}I-fibrinogen bound was calculated from a double reciprocal plot[12] of the binding data obtained after subtracting values for nonspecific binding (Fig. 1, left-hand inset). If we assume uniform labelling of fibrinogen and a molecular weight of 340,000 (ref. 13), we can estimate that 50,000 molecules of ^{125}I-fibrinogen per platelet were bound to ADP-stimulated platelets with the apparent dissociation constant of 1.5×10^{-7} M.

Thrombin in trace concentrations also stimulates human platelets[14]. To gain further insight into the mobilisation of fibrinogen-binding sites on human platelets we compared the effect of trace amounts of thrombin with that of ADP. In preliminary experiments we determined that a low concentration of thrombin (0.05 U ml^{-1}), is blocked by hirudin (0.1 U ml^{-1}) in terms of thrombin's action on human fibrinogen. Thus, after exposure of platelets to thrombin, its enzymatic activity toward fibrinogen could be neutralised. After stimulation with thrombin (0.05 U ml^{-1}) and then inactivation with hirudin, we observed specific binding of ^{125}I-fibrinogen with remarkably similar characteristics to those seen after stimulation with ADP (Fig. 1). We estimate that 44,000 molecules of fibrinogen bound with the apparent dissociation constant of 1.8×10^{-7} M (Fig. 1, right-hand inset). Thus traces of thrombin can also induce mobilisation of platelet-binding sites for plasma fibrinogen, a process shown to occur after stimulation of human platelets with ADP[15]. Because thrombin is almost instantly detectable when blood vessels are wounded[16], our observation that traces of thrombin mobilise fibrinogen receptors in human platelets is important in the platelet-fibrinogen interaction.

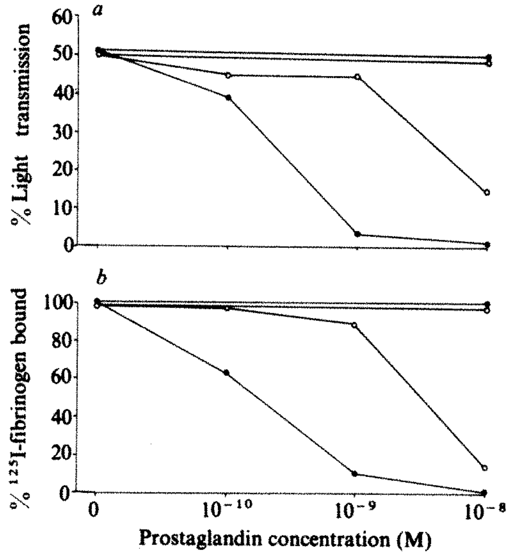

Fig. 2 Concentration-dependent effect of prostacyclin (lower two lines) and 6-keto PGF$_{1\alpha}$ (upper two lines) on binding of ^{125}I-labelled fibrinogen (*b*) and platelet aggregation (*a*) induced by ADP (●) and by thrombin (○). For platelet aggregation with ADP, fibrinogen (1.8 mg ml^{-1}) was added.

We next examined the possible regulatory role of prostacyclin in this interaction. Prostacyclin (1 nM) inhibited binding of ^{125}I-fibrinogen to human platelets stimulated with ADP, an effect that was paralleled by inhibition of ADP-induced platelet aggregation (Fig. 2). The dose–response curves for both inhibition of binding of ^{125}I-fibrinogen to platelets and inhibition of platelet aggregation were similar. Prostacyclin (10 nM) inhibited more than 80% of the binding of ^{125}I-fibrinogen to human platelets stimulated with thrombin (0.05 U ml^{-1}) and also inhibited platelet aggregation induced by the same concentration of thrombin. A 3-min pre-incubation was chosen in consideration of the relatively short lifetime of prostacyclin. However, the inhibitory effect on fibrinogen-binding lasted much longer, up to 60 min after the addition of prostacyclin to platelets.

Our experiments demonstrate that prostacyclin inhibited both ADP- and thrombin-induced mobilisation of binding sites for fibrinogen, which was paralleled by the inhibition of platelet aggregation and suggests a close association between mobilisation of fibrinogen-binding sites and platelet function. Prostacyclin raises the intraplatelet level of cyclic AMP[3,4], which can also be attained by PGD_2 (ref. 17). Indeed, PGD_2 (10 nM) also inhibited mobilisation of binding sites for fibrinogen in human platelets (results not shown). These findings suggest that mobilisation and availability of binding sites for fibrinogen are controlled by the cyclic AMP level. A decrease in cyclic AMP, resulting from ADP and thrombin action[18], promotes mobilisation of fibrinogen-binding sites, important for the subsequent formation of a platelet fibrin plug. An increase in cyclic AMP in response to prostacyclin prevents unmasking of fibrinogen-binding sites.

Although the nature of binding sites for fibrinogen on human platelets is unknown, their number after mobilisation by ADP and thrombin (50,000 and 44,000) is within the range of the 40,000 surface fibrinogen molecules per platelet determined from saturation binding of antifibrinogen Fab fragments[7]. The values established in our experiments are close to the reported number of binding sites induced by ADP[19]. We observed that sites mobilised by ADP and by thrombin are specific, saturable and of high affinity. The process responsible for mobilisation of binding sites of such affinity for fibrinogen can be related to changes in platelets induced by ADP and by a low concentration of thrombin. The changes include transformation from discoid to spherical, protrusion of several pseudopods and distension of the lumen of surface-connecting canaliculi[20]. These changes are accompanied by a decrease in adenylate cyclase activity and by the increase and redistribution of binding sites for lentil lectin demonstrated by Feagler *et al.*[14]. Increased and transient association of fibrinogen with human and rabbit platelets undergoing ADP-induced shape change was observed by Mustard *et al.*[21].

Note that the platelet-fibrin plug formed at the site of a vascular wound does not expand beyond its immediate zone or occlude the lumen of the injured vessel[5]. The inhibitory effect of prostacyclin produced by the vessel wall on mobilisation of fibrinogen-binding sites on human platelets may limit the size of the platelet-fibrin plug *in vivo*. Furthermore, this inhibitory action of prostacyclin can explain its protective effect on platelet consumption in extracorporeal circulation[22] because the interaction of platelets with foreign surfaces requires the presence of fibrinogen[23]..

Bovine thrombin, hirudin, adenosine, AMP, ADP and ATP were purchased from Sigma. Prostacyclin 6-keto $PGF_{1\alpha}$ and PGD_2 were obtained from Drs E. Nishizawa and J. Pike, Upjohn Co. This work was supported by the USPHS grants HL-24119 and HL-08339 and by the Medical Research Service of the Veterans Administration.

A Con A-stimulated T-cell hybridoma releases factors affecting haematopoietic colony-forming cells and B-cell antibody responses

John W. Schrader, Bernd Arnold & Ian Clark-Lewis

The Walter and Eliza Hall Institute of Medical Research, Post Office,
Royal Melbourne Hospital, Victoria 3050, Australia

The major role of the thymus-dependent class of lymphocytes (T cells) seems to be regulatory. With the exception of cytotoxic T cells, T-cell subsets act by modulating the function of other T and B lymphocytes[1,2] and macrophages[3], and also the progenitors of erythrocytes, monocytes and myeloid cells[4–7]. Most of these regulatory effects are mediated by humoral factors, but despite convincing evidence that T cells are essential for the production of such factors, in many instances it has been difficult to demonstrate conclusively that the T cells actually synthesise the factors[7]. Factors stimulating the formation of myeloid colonies in agar can be produced by a T-cell lymphoma, EL4 (ref. 8), and by a hybridoma formed by the fusion of a T-cell lymphoma with pokeweed mitogen-stimulated spleen cells, although in this case it was not possible to demonstrate directly that the non-tumour parent had been a T cell[9]. Here we report that a cloned T-cell hybridoma can be induced to release factor(s) stimulating both the growth of haematopoietic colony-forming cells and the B-cell response to antigen. Incubation of the hybridoma with the T-cell mitogen concanavalin A (Con A), was required for the production of these activities, which were detectable 24 h after addition of the Con A. These activities were not produced when the parental tumour (BW5147) was incubated with Con A.

The hybridoma was formed as described elsewhere[10] by fusing a hypoxanthine–aminopterin–thymidine-sensitive variant of a T-cell lymphoma (BW5147) with blast cells isolated from the lymph nodes of mice immunised with keyhole limpet haemocyanin (KLH)[11]. Hybridomas resulting from the fusion were initially cloned by limiting dilution and the Con A-reactive clone,

Table 1 The colony-stimulating activity of supernatants of hybridoma cells stimulated with Con A

Supernatant from cultures containing:	Colonies per dish
T-cell hybridoma cells	0, 0
T-cell hybridoma + Con A (0.5 $\mu g\ ml^{-1}$)	83, 90
T-cell hybridoma + Con A (5 $\mu g\ ml^{-1}$)	160, 126
TKA	0, 0
TKA + Con A (0.5 $\mu g\ ml^{-1}$)	0, 0
TKA + Con A (5 $\mu g\ ml^{-1}$)	0, 0
Spleen cells + Con A (5 $\mu g\ ml^{-1}$)	81, 70

Hybridoma cells (3×10^5) were incubated for 24 h in 2 ml of Dulbecco's modified Eagle's medium (DMEM) supplemented with 2-mercaptoethanol (5×10^{-5} M), L-asparagine (3×10^{-4} M), glutamine (2.8×10^{-3} M), 10% fetal calf serum (FCS) and Con A (Pharmacia) at the indicated concentrations. Supernatants were prepared by centrifugation and 0.1-ml aliquots placed in 35-mm plastic Petri dishes to which were added 1-ml aliquots of 0.3% Bacto-agar (Difco) in the medium described above minus 2-mercaptoethanol; each ml contained 5×10^5 viable nucleated cells from the femoral shafts of CBA/H/Wehi mice. Also included were control dishes containing 0.1 ml of the supernatants of cultures in which the T-cell lymphoma TKA was incubated with Con A, and control dishes containing 0.1 ml of the supernatant of 48-h cultures of 50×10^6 C57BL/6 spleen cells in 10 ml of medium with Con A (5 $\mu g\ ml^{-1}$). Colonies were counted with a dissecting microscope on day 7. Morphology of colony cells was determined by plucking individual colonies and then either drying and staining them with aceto-orcein, or smearing and staining them with Giemsa stain.

0028-0836/80/020197—03$01.00

designated 1.23, was then recloned in agar. It expressed both the Thy 1.1 antigen of the AKR-derived BW5147 tumour and the Thy 1.2 antigen of the CBA lymph-node donor, and possessed 79 chromosomes.

The hybridoma 1.23 did not bind KLH, as determined with fluorescein-conjugated KLH on the fluorescence-activated cell sorter (B.A., F. L. Battye and J. F. A. P. Miller, unpublished observations). Furthermore, the addition of KLH, either in soluble form or presented on peritoneal exudate cells, did not result in the release of regulatory factors. Thus, we have no evidence that the hybridoma 1.23 has receptors for, or is sensitive to, KLH.

We were aware of the reported instability of T-cell hybridomas. Therefore, we have been careful to store multiple aliquots of both the original clone and subsequently recloned sublines in liquid nitrogen, always recloning in agar after thawing. Experience has shown that the chromosome number is not stable and we have observed chromosome loss in continuously passaged sublines, in some cases without loss of the ability to release regulatory activities. We are exploring the possibility that chromosomal loss may result in functional variants that will aid in the investigation of the number of molecules responsible for the observed biological activities and the mechanism of their release.

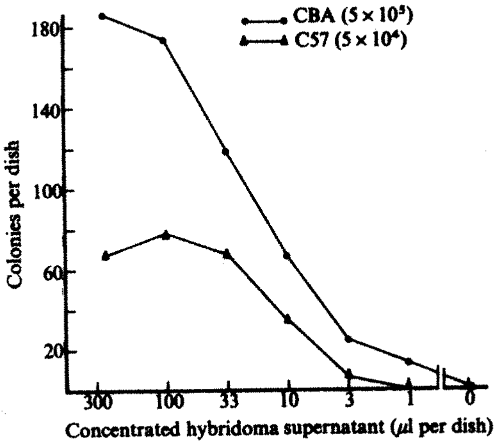

Fig. 1 The colony-forming response of bone marrow from CBA and C57BL/6 mice to supernatants of cultures of Con A-stimulated hybridoma cells. Agar cultures were carried out as described above and contained either 5×10^5 viable nucleated CBA bone marrow cells or 5×10^4 C57BL/6 bone marrow cells. The hybridoma supernatant was prepared from cells cloned twice in agar and grown in DMEM containing 10% FCS and 5×10^{-5} M 2-mercaptoethanol, by incubating 50×10^6 cells in 50 ml of medium without FCS, together with 5 μg ml^{-1} of Con A (Pharmacia). After 24 h the cell-free supernatants were collected by centrifugation and concentrated ninefold in an Amicon stirred cell with a 10,000 molecular weight cutoff membrane (Amicon YM10); they were sterilised by filtration through a 0.45-μm filter (Millipore).

Table 1 shows an experiment demonstrating Con A-dependent secretion by hybridoma 1.23 of factor(s) stimulating the growth of colonies in semi-solid cultures of normal CBA bone marrow cells. Differences were noted in the effects of supernatants of stimulated 1.23 cells on bone marrow cells from two strains of mice. Figure 1 demonstrates the effects of various amounts of concentrated supernatant from a culture of Con A-stimulated hybridoma cells, on the numbers of colonies in cultures of bone marrow cells from two mouse strains, CBA (plated at 5×10^5 per dish) and C57BL/6 (plated at 5×10^4 per dish). In both cases, colony numbers varied linearly with the number of cells cultured (data not shown). As shown in Fig. 1, in these culture conditions, the frequency of colony-forming cells was higher (by a factor of 4) in C57BL/6 bone marrow than in CBA bone marrow. Also, C57BL/6 colonies contained either macrophages or granulocytes or both, whereas up to 30% of the CBA colonies contained large multinucleate cells resembling megakaryocytes, together with blast cells and cells with annular or lobed nuclei, the remaining colonies consisting of blast cells and granulocytes or mixtures of granulocytes and macrophages.

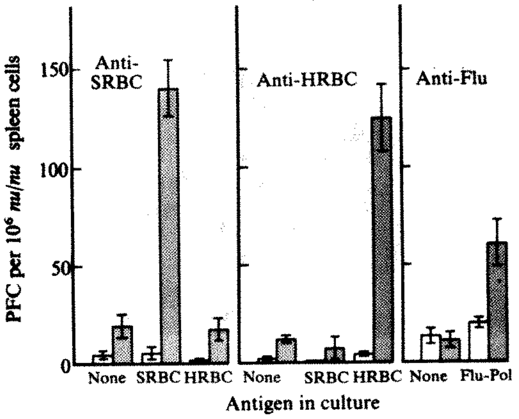

Fig. 2 The effect of supernatants of Con A-stimulated hybridoma cells on the B-cell antibody response to three antigens. Microwell cultures of *nu/nu* spleen cells containing no antigen, sheep red blood cells (SRBC) (10^6 per well), horse red blood cells (HRBC) (10^6 per well) or fluorescein-conjugated polymerised flagellin (Flu-Pol) (20 ng per well)[16], were cultured either with (hatched columns) or without (open columns) hybridoma supernatant (20%) for 4 days. Cultures incubated with erythrocyte antigens were divided in half and assayed against both SRBC and HRBC for plaque-forming cells (PFC). Cultures containing Flu-Pol were divided in half and assayed against fluorescein-bearing SRBC[16], and SRBC, the difference in PFC numbers being shown as Flu-specific PFC. Results are expressed as the mean ±s.e.m. of eight replicate cultures. The direct addition of Con A to the cultures, either with or without antigen, had no effect (data not shown). The cultures, in Linbro flat-bottomed trays (76-003-05), contained 10^6 viable nucleated BALB/c *nu/nu* spleen cells in DMEM (0.25 ml) supplemented with 5% FCS, 5×10^{-5} M 2-mercaptoethanol, 10 mM HEPES, 2.8×10^{-3} M glutamine and 3×10^{-4} M asparagine. The hybridoma supernatant was prepared and concentrated as described in Fig. 1 legend from cells cloned twice in agar.

Similar results were obtained using medium conditioned by Con A-stimulated spleen cells. Furthermore, there are other indications of differences between various haematopoietic progenitor cells in these two strains. Thus, the granulocyte–macrophage colony-forming cells in C57BL/6 bone marrow are twice as frequent and are much more sensitive to the colony-stimulating factor elaborated by endotoxin-stimulated mouse lung than are those from CBA mice[12]. Furthermore, in cultures stimulated by pokeweed mitogen-stimulated spleen cells, the frequency of mixed or erythroid colonies in fetal liver[13] or adult bone marrow (G. R. Johnson, in preparation) is markedly higher in the CBA than the C57BL/6 strain. Future study should determine both the nature of the colony-forming cells stimulated by the hybridoma supernatants and whether separate molecules are responsible for the growth of the different colonies.

Figure 2 shows the results of an experiment demonstrating that the hybridoma 1.23 supernatant affected B lymphocytes, allowing cultures of spleen cells from congenitally athymic (*nu/nu*) mice to develop an antibody response to the thymus-dependent antigen, sheep erythrocytes. Both the hybridoma supernatant and the antigen were required for a response. This effect of the supernatant was similar to that achieved with medium conditioned by Con A-stimulated spleen cells, and seems to be functionally equivalent to the T-cell replacing factor (TRF) described by Schimpl and Wecker[14]. This effect, although requiring the presence of antigen, was non-antigen specific. Thus, the response to a second heterologous erythrocyte, horse erythrocyte, was also enhanced (Fig. 2). The results show that cross-reaction between these antigens was not detected. Furthermore, the response to a third, quite unrelated antigen, fluorescein-conjugated polymerised flagellin (Flu-Pol) was also enhanced. The enhancement of the thymus-independent response to this antigen is consistent with the notion that the hybridoma supernatant is acting subsequent to B-cell activation, amplifying the antibody response in a non-antigen specific way[14,15].

These observations are interesting from several points of view. First, the availability of a clonal cell line offers great advantages for the reproducible, large-scale preparation of material for biochemical analysis. Preliminary experiments suggest that the hybridoma supernatants also support the *in vitro* proliferation of T lymphocytes and pluripotential stem cells, indicating that several different factors could be involved. It will be important to determine how many molecular species are involved in these activities and, if there are more than one, what relationship there may be between them. In this connection, it is of interest that analyses of medium conditioned by Con A-stimulated spleen cells, the biological activity of which seems to parallel in all respects that of the hybridoma supernatants, show that the B-cell effect and the colony-stimulating activities are separable biochemically, indicating the presence of at least two types of regulatory molecule (I.C.-L. and J.W.S., unpublished data).

Second, the observation that a cloned cell line with definite T-cell markers produces regulatory factors when stimulated with Con A in the same manner as do spleen cell suspensions, indicates that T cells themselves can produce these factors. Third, the demonstration that supernatants derived by stimulation of a cloned cell line enhance antibody responses to several antigens (Fig. 2), is against the notion that the 'T-cell replacing' activity produced by Con A-stimulated spleen is not really non-antigen specific, but is due to the release of a mosaic of antigen-specific T-cell factors on polyclonal stimulation of T cells.

Finally, functional T-cell hybridomas have proven more elusive than their B-cell counterparts. Studies of the conditions required for activation of this hybridoma by Con A may aid in defining conditions for the optimal induction and function of T-cell hybridomas. Furthermore, assays for the release of soluble factors such as those described here may prove useful as screening procedures for the detection of stimulation of T-cell hybridomas by specific antigen.

We acknowledge the advice and support of Dr J. F. A. P. Miller in the production of the T-cell hybridoma. Development of specific suppressor cells in hypoinsulinaemic mice

Wlodzimierz Ptak, Maria Rewicka & Maria Kollat

Department of Experimental and Clinical Immunology, Institute of Microbiology, Copernicus Medical Academy, 31-121 Kracow, Poland

Mice and rats injected with alloxan or streptozotocin develop permanent diabetes, characterised by deficient insulin production. It has been demonstrated that hypoinsulinaemia in mice leads to significant loss of lymphatic tissue[1,2], and these diabetic animals cannot develop contact sensitivity[1] or efficient graft rejection[3,4]. Administration of insulin partially restored these responses[1,4] and also caused an increase in the weight of the thymus and spleen[1]. Similar suppression of T cell-dependent phenomena has been observed in surgically pancreatectomised rats[5]. Lymphocytes of these hypoinsulinaemic animals show significantly decreased *in vitro* responses to plant lectins[2,6,7] and generate only low levels of cytotoxic effector cells[2,7]. We previously showed that cells of normoglycaemic oxazolone-sensitised mice cannot transfer significant contact sensitivity reactions into diabetic recipients[1] indicating that the milieu of hyperglycaemic insulin deficient animals cannot support all the activity of immune T cells. By mixing immunised T cells from control and diabetic mice and transferring the mixtures into normal recipients we now show that the non-supportive milieu in diabetic animals may be due to active suppression rather than to athrepsis.

CBA and DBA/2 inbred male mice were rendered diabetic by intravenous (i.v.) injection of alloxan (75 mg per kg). Only mice with blood glucose levels exceeding 400 mg per 100 ml and showing no signs of diabetic disease were incuded in the experiments[1]. Normoglycaemic mice were sensitised by application of 0.1 ml of 7% picryl chloride (PCL) or 3% oxazolone (OX) to the skin of the clipped abdomen[8]. Diabetic mice were sensitised 4 days after alloxan administration with lower doses of PCL (3%) and OX (1%) than normal mice because higher doses tend to be toxic in these mice. Normal mice respond similarly to both antigen doses[8,9]. Four days later single cell suspensions were prepared from the spleens and peripheral lymph nodes of the diabetic and control animals. In some experiments cells of diabetic CBA mice were treated with anti-Thyl serum and complement[10] or T cells were isolated with the help of nylon wool columns[11]. Cells from sensitised normoglycaemic animals (4×10^7) were injected i.v. into normal recipients. Some recipients also received 2×10^7 cells from diabetic mice which had or had not been previously immunised. Immediately after transfer the mice were challenged on the ear with 1% PCL or OX in olive oil and the increment of ear thickness measured after 24 h[8].

The results of such an experiment (Table 1) shows that nylon non-adherent Thy 1 positive cells from immunised diabetic mice abrogate in an antigen-specific way the ability of normal immune T cells to transfer contact sensitivity. Thus, a lack of insulin changes an otherwise immunogenic sensitising procedure into one which preferentially activates suppressor T cells.

The induction of specific suppressor cells by antigen in hypoinsulinaemic environment could be explained in a number of ways. One possibility is that distinct subpopulations of T lymphocytes show selective suspectibility to high glucose levels (or high osmotic pressure). This interpretation, although not disproved, seems unlikely since T helper cells function quite well *in vitro* at glucose concentrations much higher than those present in diabetic animals[12]. Another possibility, and the one we favour, is that the activity of lymphocytes is directly influenced by the insulin level. The effects of insulin may depend on its overall action on metabolic pathways which could explain the general loss of lymphatic tissue in diabetic animals. Some

Table 1 Suppression of passive transfer of contact sensitivity (CS) by lymphocytes of diabetic animals

Lymphocytes of diabetic animals, specificity and treatment	CS reaction ($\times 10^{-3}$ cm) PCL	OX
No cells (−ve control)	1.7 ± 0.25	2.4 ± 0.36
No cells (+ve control)	6.5 ± 1.04	8.3 ± 1.33
PCL	3.0 ± 0.63	8.4 ± 0.87
OX	7.2 ± 0.74	4.9 ± 0.56
Not sensitised	7.0 ± 0.37	8.0 ± 0.60
PCL, purified T cells	2.2 ± 0.41	ND
PCL, anti-Thy 1 treated	7.8 ± 0.51	ND
OX, purified T cells	ND	4.0 ± 0.34

Normal CBA recipients were injected with 4×10^7 cells of normal animals sensitised with PCL or OX 4 days previously, mixed with 2×10^7 cells from diabetic animals which had (or had not) been sensitised with either PCL or OX 4 days before transfer. In some experiments cells from hyperglycaemic mice were purified on nylon wool columns (purified T cells) or treated with anti-Thy 1 serum and C′ before being injected to the hosts. This serum killed >90% nylon column purified T cells. Mice were challenged on the ears with the homologous hapten. Each group consisted of six to eight mice. Similar results were obtained with DBA/2 mice. Results are given as mean ±s.d. +ve control refers to animals which received immune normal cells only; −ve control refers to mice which received no injection of cells (nonspecific ear swelling).

selectivity of insulin action, however, argues against this simple scheme. It has been found that insulin augments the *in vitro* cytotoxicity of sensitised lymphocytes[13] and insulin receptors have been demonstrated on cytotoxic lymphocytes[14] as well as on cells activated with concanavalin A[15]. The majority of blood lymphocytes do not express demonstrable insulin receptors which suggests that subsets of T lymphocytes may differ in their expression and thus may be selectively sensitive to insulin deficiency.

A large body of data has accumulated which suggests that cytotoxic effector cells and suppressor T lymphocytes share several characteristics[16,17], including the expression of hormone receptors[14], which are not shared by helper cells. If these similarities extend to insulin receptors we would then postulate a direct effect of the lack of insulin on the expression of suppressor cell activity. Since the lack of insulin increases suppressor cell activity, as demonstrated above, our results could suggest that the presence of insulin is an important factor in damping down normal suppressor cell activity. This postulate would predict that subjects with deficient levels of insulin would be more susceptible to infection because of hyperactivity of their suppressor cells. However, since the activation of suppressor cells has been shown to be the result of a complex series of interactions between T cell sets and since it has also been shown that the activity of cells outside of the suppressor circuit can influence the levels of suppression which become manifest after immunisation[18], our results do not indicate directly that the suppressor cell itself is the target of insulin mediated control. Further studies using antisera which define functionally distinct T cell subsets are required before we can definitely say how the lack of insulin leads to increased suppressor cell activity. We are also attempting positive selection studies, using insulin columns to directly test the nature of the cells which binds to the columns. The fact that insulin has been shown to increase the activity of sensitised killer lymphocytes[2,7], and that its lack appears to increase the level of suppressor cell activity should not be taken as evidence that the putative insulin receptors of these two sets of T cells are in any way different. The possibility that a single agonist can have two opposing effects depending upon dose, should be taken into consideration. The observations, however, that discrete subpopulations of T lymphocytes carry receptors for various hormones (for example, growth hormone[19] or histamine and adrenaline[20]) make our hypothesis of selective expression of insulin receptor tenable and testable.

Phototransduction in the fly compound eye exhibits temporal resonances and a pure time delay

Andrew S. French

Department of Physiology, University of Alberta, Edmonton, Alberta, Canada T6G 2H7

Photoreceptor cells in both vertebrates and invertebrates respond to a flash of light with a slow graded change in membrane potential, which is generally depolarising in invertebrates and hyperpolarising in vertebrates. Although some of the early photochemical and biochemical stages of the transduction process have been elucidated in both cases[1,2], these reactions are fast compared with the time course of the electrical response, which is typically hundreds of milliseconds long. To explain this slow response in the eye of *Limulus*, Fuortes and Hodgkin[3] proposed a mechanism in which the light signal passes through a cascade of simple low pass filters. The model was later defined more specifically in terms of a chain of chemical reactions linked together through products and reactants[4], and has been used with small modifications and different numbers of stages to account for the behaviour of various vertebrate and invertebrate photoreceptors including the fly compound eye[5,6]. I have now obtained evidence that phototransduction in the fly in small signal conditions involves underdamped resonance behaviour and a significant pure time delay, neither of which can be accounted for by the conventional cascade model.

The frequency response function is an alternative means of characterising the dynamic behaviour of a photoreceptor, and yields an identical description to that given by the response to a brief flash of light if the photoreceptor behaves linearly. In practice the frequency response method is more useful than the flash method because it allows a photoreceptor to be examined in small signal conditions with relatively small light fluctuations where behaviour is linear. When the white noise stimulation technique is used to measure the frequency response function it is possible to characterise a photoreceptor very efficiently and simultaneously to measure the linearity and signal to noise level of the system through the coherence function[6].

In the frequency domain the long-delayed response of photoreceptors becomes a phase lag which increases with frequency and there is also a substantial amplitude attenuation with increasing frequency. The Fuortes and Hodgkin model predicts these effects but also predicts a maximum phase lag asymptote the value of which is given by 90° multiplied by the number of stages in the cascade. This asymptotic phase lag has never been demonstrated clearly and most published frequency response functions for photoreceptors show a phase lag which is

0028–0836/80/020200—03$01.00

unbounded with increasing frequency. In previous investigations of the fly photoreceptor system[6,7] we tried to find a phase lag asymptote and tentatively suggested that it occurs at a lag of 450°, characteristic of a five-stage cascade. However, examination of the coherence functions which we obtained for this preparation reveals that in the frequency range where the asymptote should appear, which is above 100 Hz in the fly, the signal to noise ratio is so low that there is little statistical confidence in the measurements. Because this problem arises from the inherent noise level of the photoreceptor, the same difficulty will apply to the flash response measurement, but it will be the accuracy of the most rapidly changing regions of the response which are unreliable.

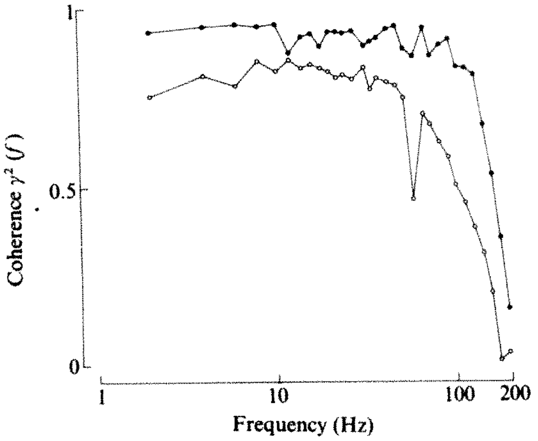

Fig. 1 Coherence function, $\gamma^2(f)$, for phototransduction in a fly photoreceptor cell. The open circles are from an experiment conducted with the conventional white noise technique using 25 sequences of noise, each lasting 512 ms. The input and output data were sampled at 1-ms intervals and processed using the fast Fourier transform. The filled circles are from the same experiment but with each of the 25 sequences being presented 10 times and the average response taken. The improvement in signal to noise ratio may be quantified by use of the expression $\gamma^2(f) = 1/(1 + N(f)/S(f))$, where $S(f)$ is the signal power and $N(f)$ is the noise power at frequency f[11]. Applying this equation at 100 Hz gives more than a fivefold improvement in signal to noise power ratio. Solid lines are drawn through the data points for visual clarity. The large dip in the unaveraged data is at 60 Hz, the a.c. power frequency, and represents unavoidable experimental pick up. It is also reduced substantially by the averaging process because it is uncorrelated with the stimulus.

I repeated the frequency response function measurements on the fly photoreceptor system using an averaging technique to improve the signal to noise ratio. The technique consists of stimulating the eye with repeated bursts of pseudo-random noise patterns of light intensity while averaging the responses to identical patterns. This averaging reduces the uncorrelated noise from the response and the averaged signal is processed as if it were the response to a single presentation of the random input. The experiments were conducted on the R1-6 photoreceptors of the compound eye of *Phormia regina* using a green light-emitting diode with peak output at 560 nm. Intact flies were mounted in wax and intracellular recordings of membrane potentials were made by glass microelectrodes filled with 3 M KCl and having resistances in the range 50–100 MΩ. The microelectrode was advanced through the back of the eye and a platinum ground electrode was placed in the thorax. Details of the experimental procedures and the averaging technique are given elsewhere[8,9].

Figure 1 shows a comparison of the coherence function measured for a photoreceptor with and without the averaging technique. There is a substantial improvement in the signal to noise ratio, particularly in the critical frequency region of 100–200 Hz where the phase lag asymptote should appear. Figure 2 shows the frequency response function between light fluctuations and membrane potential fluctuations for the same experiment as Fig. 1. The improved signal to noise ratio produces a smooth frequency response function to 200 Hz, which compares favourably with our published data[6,7].

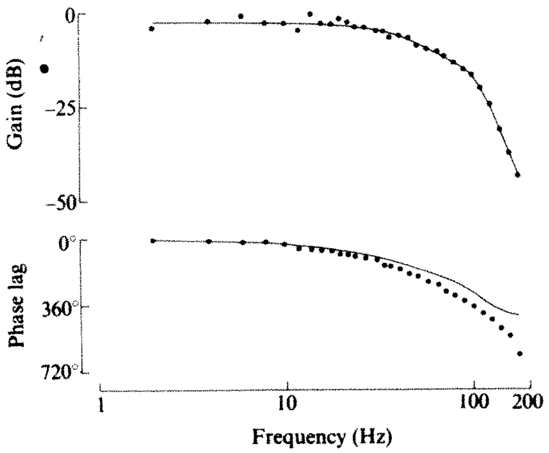

Fig. 2 Frequency response function between light fluctuations and fluctuations in membrane potential in the same photoreceptor cell as for Fig. 1. The mean current through the light emitting diode was 5.6 mA which gives a peak response of about 10 mV in a dark adapted photoreceptor. The mean intensity was modulated to a depth of 75% by the pseudo-random noise stimulus. The solid lines are the predicted response from a linear system consisting of a cascade of two first order poles with time constants of 1.13 and 1.56 ms and two second order poles with time constants of 3.83 and 1.49 ms and damping factors of 0.79 and 0.25, respectively. The phase data points fall progressively below the predicted response with increasing frequency and the difference between these two sets of values is shown in Fig. 3.

A low pass frequency response function can be factorised into an expression containing integrating terms, $(j\omega)^{-1}$, first order poles, $(1 + j\omega\tau)^{-1}$, and second order poles $(1 + 2j\zeta\omega\tau + (j\omega\tau)^2)^{-1}$, where $j = \sqrt{-1}$, ω is natural frequency, τ represents time constants, and ζ represents damping factors[10]. Integrating terms give rise to a constant phase lag of 90° at all frequencies and so were not considered further because of the reliable low frequency phase asymptote of 0°. The Fuortes and Hodgkin model would produce a series of first order poles, with each stage contributing a single time constant. Second order poles represent underdamped or resonant behaviour for $\zeta < 1$, or can be factorised simply into two first order poles for $\zeta > 1$. Pure time delay may also be present in a linear system and it produces a phase lag equal to the product of the delay and the frequency, without affecting the gain of the response.

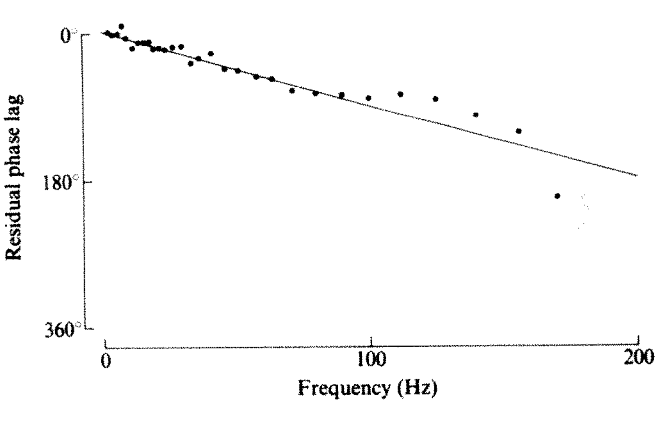

Fig. 3 Difference between the experimental phase lag of Fig. 2 and the predicted phase lag for the linear system which fits the gain data. The residual phase lag has been plotted on linear axes and fitted with a straight line by linear regression. The slope of the straight line corresponds to a delay of 2.48 ms and the linear regression coefficient is 0.95.

Frequency response functions of the type illustrated in Fig. 2 were fitted by an iterative minimum mean square error technique in which an initial estimate of the number and types of poles and their time constants was made. Then a computer program varied each component up and down in value while computing total square error between the estimate and the experimental data. The varied values producing the smallest error were then used as new estimates while the size of the variation was reduced and the process repeated until the variation was below 1%. The fitting process was applied to the gain portion of the response because this is independent of any delay. Initial attempts to fit the experimental data with first order poles were unsuccessful compared to the accuracy with which the data could be fitted using first and second order poles. The solid line in Fig. 2 is the fit produced by two first order poles and two second order poles. This model also gave the best fit to the data from 12 separate experiments, with average time constants and damping factors of: $\tau_1 = 0.92$ ms, $\tau_2 = 1.15$ ms, $\tau_3 = 3.28$ ms, $\zeta_3 = 0.88$ and $\tau_4 = 1.41$ ms, $\zeta_4 = 0.35$. The model did not account adequately for the phase data, which always lagged further than the prediction at higher frequencies. Because the only behaviour that could explain this discrepancy is a pure time delay the difference between the predicted and actual phase data was plotted on linear axes and fitted with a linear regression line, as illustrated in Fig. 3. This produced a good fit in all experiments with a mean delay value of 2.85 ms and a mean correlation coefficient of 0.93.

These results show that the linear cascade model is inadequate to account for phototransduction in the fly and a model must be constructed which predicts the underdamped behaviour and the pure time delay.

Ca^{2+} transmembrane fluxes and nerve growth factor action on a clonal cell line of rat phaeochromocytoma

Gary Landreth, Paul Cohen* & Eric M. Shooter

Department of Neurobiology, Stanford University School of Medicine, Stanford, California 94305

Nerve growth factor (NGF) is a polypeptide hormone which has a fundamental role in the development and maintenance of sympathetic and some sensory neurones[1,2]. The primary event by which NGF exerts its actions on these neurones probably involves the recognition of specific membrane-located receptors[3–5]. A clonal cell line of rat phaeochromocytoma, PC12, responds to NGF by cessation of division and expression of several properties characteristic to mature sympathetic neurones, including neurite outgrowth[6,7]. These cells also possess cell-surface NGF receptors, a fraction of which are occupied at NGF concentrations which elicit NGF-specific responses in these cells (G.L. and E.M.S., unpublished results). The manner in which binding of NGF to its receptor is translated into the subsequent morphological and biochemical events is not yet known but is being investigated. One possible transducing mechanism which has been suggested involves transient changes of intracellular cyclic AMP levels[8,9]. The divalent cation Ca^{2+} has been proposed as a second messenger in the mechanism of action of peptide hormones such as insulin[10,11], which also initiates its action through membrane-bound receptors. Here, we have investigated the hypothesis that the mechanism of NGF action on PC12 cells may involve modulation of calcium transmembrane fluxes. The evidence shows that NGF has no significant influence on calcium fluxes as measured by uptake and efflux rates of ^{45}Ca in PC12 cells.

PC12 cells were grown in Dulbecco's modified Eagle's medium containing 4.5 mg l^{-1} glucose, supplemented with 10% fetal calf serum and 5% horse serum. For the measurements of calcium fluxes in single cell suspensions of PC12 cells, the culture medium was removed and the cells washed three times with 10 ml of Tris-buffered Gey's solution (TBG), *p*H 7.4, containing 1.5 mM Ca^{2+} and 0.1% bovine serum albumin. The cells were centrifuged for 3 min at 500*g*, the supernatant discarded and the pellet resuspended in the same buffer at a final concentration of 10^6 cells ml^{-1}. Cell viability was evaluated before and after the calcium flux measurements by trypan blue exclusion and was always 85–95%. The cells were preincubated for 40–60 min with gentle shaking at 37 °C in the absence of ^{45}Ca for the uptake experiments or in the presence of ^{45}Ca for efflux experiments.

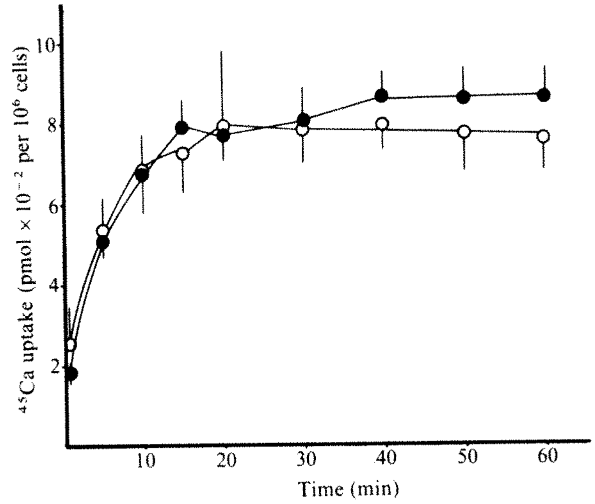

Fig. 1 ^{45}Ca uptake by PC12 cells. A suspension of PC12 cells (8 ml of a suspension of 10^6 cells ml^{-1}) was preincubated with gentle shaking for 40 min at 37 °C in TBG. At the end of this preincubation ^{45}Ca was added to one half of the sample to give a final specific activity of 30 μCi μmol^{-1}, and NGF was added to the remaining half of the sample together with ^{45}Ca to the same final specific activity. The ^{45}Ca content of the cells was determined by layering 0.1 ml of the cell suspension on the top of a two-step sucrose gradient (50 μl of 0.15 M and 150 μl of 0.3 M sucrose in a 400-μl Beckman microfuge tube), centrifuging for 30 s in the microfuge, rapidly freezing the tube and cutting off the section containing the cell pellet. The pellet in the tube tip was treated overnight in 0.4 ml of Protosol, scintillation fluid added and the radioactivity determined. Each point represents the mean (±s.d.) of three separate experiments. ●, Control cells; ○, cells incubated with 3 nM NGF.

The effect of NGF on ^{45}Ca uptake was measured on suspensions of PC12 cells (Fig. 1). The uptake reaction was initiated by the addition of ^{45}Ca alone or with 3 nM NGF. NGF had no effect on either the rate or magnitude of the ^{45}Ca uptake reaction. Similar results were obtained if NGF (3 nM) was added at the beginning of the preincubation period (data not shown).

Table 1 ^{45}Ca efflux from preloaded PC12 cells attached to a substratum

	Calcium preloading period (h)	Experiment	Radioactivity released (d.p.m. ^{45}Ca ml^{-1}) 30 min		60 min		*n*
a	1	1 Control	1,450 (±150)	$P<0.4$	1,590 (±130)	$P<0.4$	3
		NGF	1,620 (±230)		1,740 (±180)		3
		2 Control	1,060 (±120)	$P<0.5$	1,140 (±120)	$P<0.5$	4
		NGF	1,110 (±40)		1,160 (±90)		4
b	48	Control	1,140 (±150)	$P<0.4$	1,280 (±120)	$P<0.1$	3
		NGF	1,010 (±110)		1,100 (±80)		3

a, PC12 cells (log phase) were washed with TBG as described in the text and 3×10^6 cells were plated onto polylysine-treated 60-mm tissue culture dishes. ^{45}Ca was added immediately to a final specific activity of 1.3 μCi μmol^{-1} and cells were preincubated for 1 hr at 37 °C. The cells were rapidly washed three times in TBG or in TBG containing 3 nM NGF, 4 ml of the appropriate solution added to the dish and incubation carried out at 37 °C. After 30 or 60 min, 0.1-ml aliquots of the medium were taken in quadruplicate and radioactivity determined. In controls where there were no cells in the dish ~100 c.p.m. ml^{-1} were released from the dish. The data are presented as the mean of *n* samples; the figures in parentheses are standard deviations and *P* values were determined by Student's *t*-test. *b*, PC12 cells were grown (log phase) in Dulbecco's modified Eagle's medium to which 1.1 μCi μmol^{-1} ^{45}Ca was added 48 h before the cells were collected. The cells were removed from the tissue culture dish in the TBG containing the same concentration of ^{45}Ca, washed and then replated on polylysine-treated tissue culture dishes (60 mm, 3×10^6 cells per dish) in the same medium containing ^{45}Ca and preincubated for 1 h at 37 °C. The cells were then rapidly washed three times with calcium-free TBG or calcium-free TBG containing 3 nM NGF and 4 ml of this medium added to the dish. After 30 or 60 min, 0.1-ml aliquots of the medium were taken in quadruplicate and radioactivity determined.

The efflux of ^{45}Ca from suspensions of PC12 cells was measured after preloading the cells with ^{45}Ca for short (40 min) and long (25 h) periods. The efflux of ^{45}Ca from PC12 cells after a short preloading period is shown in Fig. 2. The exposure of the cells to 3 nM NGF produced no significant change in the rate of ^{45}Ca efflux. If the cells were preloaded for 25 h with ^{45}Ca, similar results were obtained when tested with 5 nM NGF or as much as 300 nM highly purified 7S NGF (ref. 12, data not shown). Both uptake and efflux studies were carried out with confluent cultures as well as those during log phase growth and identical results were obtained.

The efflux of ^{45}Ca from PC12 cells attached to tissue culture dishes was also investigated, as cell membrane-mediated events may be influenced by attachment of cells to a substratum. When PC12 cells (log phase) were preincubated with ^{45}Ca for 1 h on polylysine-treated tissue culture dishes (60 mm) and the efflux measured in the presence or absence of NGF (3 nM), no difference in the magnitude of the loss of ^{45}Ca was detected 30 or 60 min later (Table 1). Similarly, if the cells were preincubated for 48 h with ^{45}Ca and the efflux into calcium-free medium measured, NGF (3 nM) had no significant effect.

These results show that NGF has no demonstrable effect on transmembrane calcium fluxes, when measured with cells either in suspension or attached to a substratum. Efforts to alter intracellular calcium concentrations by addition of the calcium ionophore A23187 were unsuccessful because of the cytotoxic effects of the drug on PC12 cells in serum-free medium. When A23187 was tested in the presence of serum it had no effect on the NGF-mediated morphological differentiation. However, the binding of the drug to serum lipids rather than to the cell is a possibility which cannot be ruled out.

Schubert *et al.*[13] have recently suggested that NGF initiates its action on PC12 cells by causing a transient increase in intracellular cyclic AMP followed by a mobilisation and release of intracellular calcium stores. This conclusion was based on experiments which showed a small increase in the efflux of ^{45}Ca from NGF-treated cells compared with untreated cells[13]. The experiments reported here do not show an NGF-mediated alteration of ^{45}Ca efflux from cells in suspension when either low concentrations (3 nM) of NGF or high concentrations (300 nM) of 7S NGF were added. Moreover, the data shown in Table 1*b* were obtained in the same conditions as described by Schubert *et al.*[13] except that the NGF concentration was substantially lower. The lower NGF concentrations were chosen because the PC12 NGF receptors are fully saturated at 3 nM NGF (G.L. and E.M.S., unpublished observations), whereas half-maximal stimulation of neurite outgrowth occurs at 0.01 nM NGF (ref. 14). The binding of NGF to its cell-surface receptor does not require calcium[15]. It is noteworthy that Schubert *et al.*[13] used 800 biological units ml^{-1} of the 7S NGF complex (~300 nM), resulting in NGF concentrations several orders of magnitude above the physiologically effective concentrations of NGF for these cells. Even when tested at this concentration we were unable to detect any NGF-mediated alteration of ^{45}Ca efflux from suspensions of PC12 cells.

The hypothesis that NGF causes a rapid but transient increase in intracellular cyclic AMP preceding the calcium mobilisation

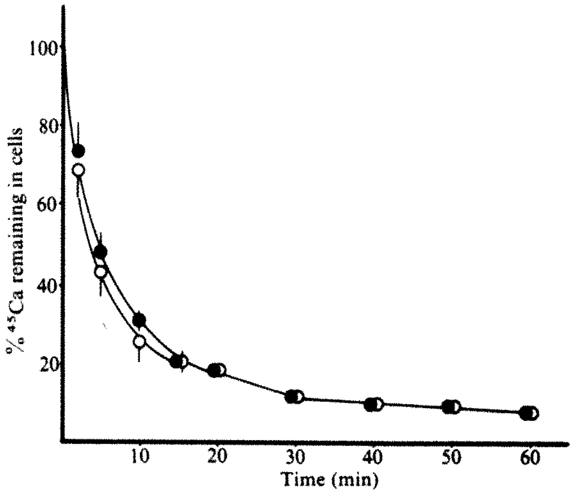

Fig. 2 ^{45}Ca efflux from PC12 cells. The time course of the ^{45}Ca efflux was measured after a suspension of PC12 cells (10^6 cells ml^{-1}) had been preincubated at 37 °C in TBG containing 5 μCi μmol^{-1} ^{45}Ca. After 60 min, 0.1-ml aliquots were taken and the cellular ^{45}Ca content determined as described in Fig. 1 legend. The radioactivity in the cells at this time was defined as 100%. The suspension was divided into two halves, each half centrifuged at 500*g* for 30 s, the supernatants discarded and the pellets resuspended with trituration in the same buffer but without ^{45}Ca. One half of the sample received no addition, and 3 nM NGF was added to the other half. The amount of ^{45}Ca remaining in the cells was evaluated by sampling 0.1-ml aliquots in triplicate at various times after transfer to the ^{45}Ca-free buffer. ●, Control cells; ○, cells incubated with 3 nM NGF. Each point represents the mean (±s.d.) of a series of three experiments, with each experiment consisting of triplicate samples. In each of the three individual experiments no significant difference between control and NGF-treated samples was observed.

in PC12 cells has also been questioned. Hatanaka *et al.*[16] could not demonstrate any alteration of intracellular cyclic AMP levels by NGF, in contrast to the findings of Schubert *et al.*[9,13]. The relationship of intracellular calcium concentrations and cellular differentiation is unclear[17], but it is possible that calcium may be involved in certain aspects of differentiation. However, in the light of the data presented here and those of others[16], the hypothesis that NGF action is mediated through cyclic AMP-dependent calcium mobilisation must be viewed with caution.

Oscillation of $[Ca^{2+}]_i$-linked K^+ conductance in bullfrog sympathetic ganglion cell is sensitive to intracellular anions

K. Kuba

Department of Physiology, Saga Medical School, Saga 840-01, Japan

The intracellular free Ca^{2+} ($[Ca^{2+}]_i$) regulates the K^+ conductance (G_K) of the many types of cell membrane[1–11]. The Ca^{2+} influx during an action potential activates this $[Ca^{2+}]_i$-linked G_K in most neurones[2–4,8–11]. In caffeine-treated sympathetic ganglion cells, however, Ca^{2+} released from an intracellular Ca^{2+} reservoir site analogous to the sarcoplasmic reticulum (SR) of the muscle (see ref. 12) causes activation of the G_K, which results in slow oscillatory hyperpolarisations (caffeine hyperpolarisation, C-hyperpolarisation)[11]. Such a release of Ca^{2+} linked to the G_K of the membrane seems important for understanding the role of the intracellular organelles in the control of membrane activities of a neurone. We report here the mechanism of the slow oscillatory hyperpolarisations recorded from the bullfrog sympathetic ganglion cell in Ringer solution. It is found that these hyperpolarisations are generated by a $[Ca^{2+}]_i$-linked G_K system and are highly sensitive to anions in an intracellular recording electrode, probably to intracellular anions.

Experimental procedures for intracellular recording from B-type neurones of paravertebrate sympathetic ganglia of the bullfrog (*Rana catesbeiana*) have been described previously[11,13,14]. Most experiments were carried out using microelectrodes filled with 1 M K_3-citrate (tip resistance 20–60 MΩ). In some experiments, electrodes were filled with 0.3 M K_2-sulphate, 3.0 M K-acetate or 3 M KCl (tip resistances 30–100 MΩ). Experiments were carried out at room temperature (20–25 °C).

When the ganglion cell was impaled with an electrode filled with 1 M K_3-citrate in Ringer, the resting membrane potential was relatively low (−40 to −50 mV), probably due to penetration injury[15]. Within a few minutes, the membrane began to hyperpolarise (repolarise), with an increase in the membrane resistance. In 10–20 min, the resting membrane potential and resistance reached a relatively high constant value (Fig. 1*Aa*, *b*). In this condition, the generation of an action potential was followed by a slow hyperpolarisation with a notable delay in many of the cells impaled (26 cells out of 38) (Fig. 1*Ab*). After a further 5–10 min, slow rhythmic hyperpolarisations appeared spontaneously in most cells (23 cells out of 38; Figs 1*Ac*, *B*, *C* and 2*Cc*). The amplitude (7.3 ± 0.8 mV (s.e.), $n = 23$) and time course (half-duration 1.6 ± 0.4 min) of these transient hyperpolarisations and the rate of their appearance (one every 6.4 ± 0.9 min, $n = 23$) remained almost constant as long as the resting potential was unchanged. Because, as will be described below, these hyperpolarisations seen in Ringer were very sensitive to intracellular anions, they will be called hereafter anion-sensitive hyperpolarisations (A-hyperpolarisations).

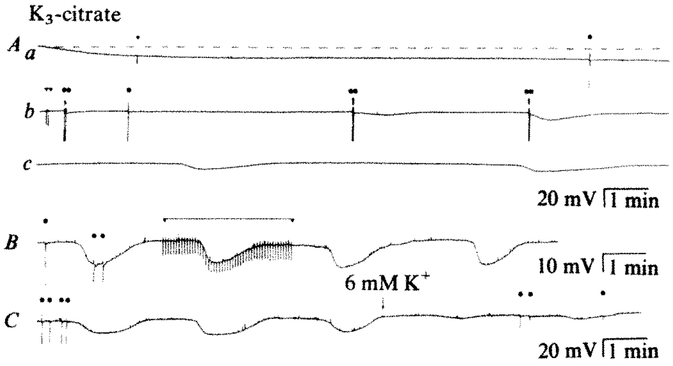

Fig. 1 Slow rhythmic hyperpolarisations (A-hyperpolarisations) recorded from three different cells. An action potential was induced by antidromic stimulation at times indicated by a closed circle (*A*–*C*). A hyperpolarising current pulse (0.3 nA, 250 ms) was applied through a recording electrode at times indicated by a triangle (*A*) or the current pulses (0.2 nA, 250 ms) were applied repetitively for the period indicated by the two triangles (*B*). *A*, Example of the time course of the membrane potential change after the penetration of the ganglion cell with an electrode filled with 1 M K_3-citrate. All the records (*a*–*c*) are continuous. The recording electrode was inserted immediately before the beginning of the record *a*. The spike component of the action potential is not shown (this is also true of the remaining figures where action potentials are shown). Note the appearance of an A-hyperpolarisation following the after-hyperpolarisation of an action potential and spontaneously occurring A-hyperpolarisations. *B*, The reductions of the membrane resistance and the amplitude of the after-hyperpolarisation of an action potential during the generation of an A-hyperpolarisation. *C*, Effects of an increase in the K^+ concentration in Ringer on A-hyperpolarisations.

The membrane resistance decreased dramatically during the generation of an A-hyperpolarisation (Fig. 1*B*). Raising the external K^+ concentration (6 mM) markedly reduced the amplitude of A-hyperpolarisations, although it depolarised the membrane only slightly (Fig. 1*C*). Conditioning membrane hyperpolarisations decreased the amplitude of the A-hyperpolarisation (Fig. 2*A*) and seemed to be reversed at a level at which the after-hyperpolarisation of an action potential was reversed (Fig. 2*B*). Thus, A-hyperpolarisations are apparently induced by an increased G_K of the membrane.

0028–0836/80/020204—02$01.00

As in the case of C-hyperpolarisations[11,13,14], A-hyperpolarisations were extremely sensitive to the external Ca^{2+} concentration ($[Ca^{2+}]_o$). Lowering $[Ca^{2+}]_o$ completely abolished A-hyperpolarisations (four cells) or decreased the rate of their appearance (three cells) in 3–5 min after the solution change (Fig. 2*C*), whereas the frequency of their appearance increased when $[Ca^{2+}]_o$ was raised. These effects of $[Ca^{2+}]_o$ were reversible. Furthermore, A-hyperpolarisations were sensitive to low temperature and inhibited by dantrolene Na (6.4 μM), as observed in the C-hyperpolarisation[11,13]. Thus, A-hyperpolarisations seem to be generated by a mechanism similar to that for C-hyperpolarisations, that is, increases in the G_K due to periodic rises in $[Ca^{2+}]_i$.

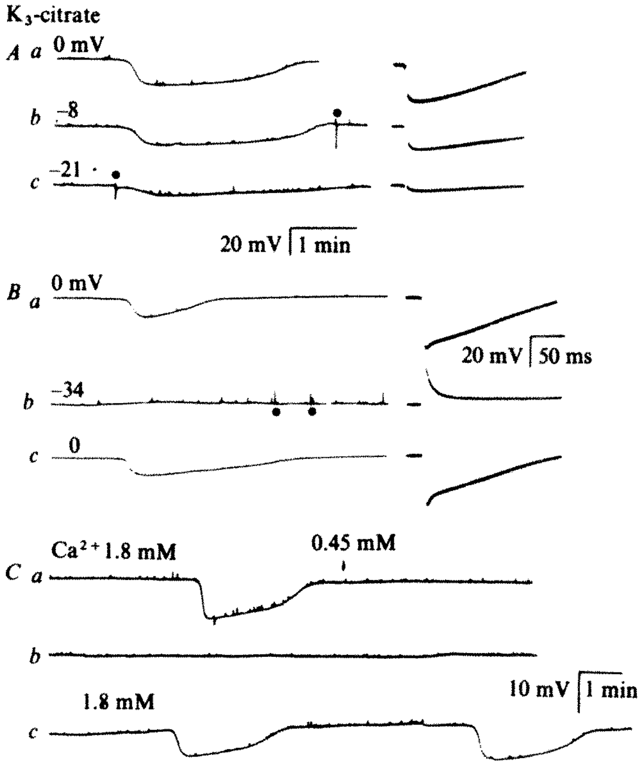

Fig. 2 *A*, *B*, Effects of conditioning membrane hyperpolarisations on the A-hyperpolarisation (left records) and the after-hyperpolarisation of an action potential (right records) in two cells. The level of membrane hyperpolarisation shown in the left side corresponds to both A-hyperpolarisations and after-hyperpolarisations of action potentials. An action potential was evoked by antidromic stimulation at times marked by closed circles in the left record of *Ab*, *Ac* and *Bb*. Action potentials are not shown in the left records of *Aa*, *Ba* and *Bc*. *C*, Effects of a reduction in the extracellular Ca^{2+} concentration in Ringer on A-hyperpolarisations. All the records are continuous. Note the disappearance of A-hyperpolarisations at a reduced Ca^{2+} concentration.

There is, however, a definite difference between the experimental conditions for recording A- and C-hyperpolarisations. The former were recorded by impaling a cell with an electrode filled with 1 M K_3-citrate in Ringer, whereas the latter were recorded with a 3 M KCl-filled electrode in a solution containing caffeine. This would imply that the species of an anion leaked out of the electrode into the cytoplasm, would determine the requirement for caffeine in the generation of oscillatory hyperpolarisations. Indeed, a very low dose of caffeine (0.1–1.0 mM) unable to induce C-hyperpolarisations augmented the amplitude and frequency of the A-hyperpolarisation, indicating that there was an increase in the apparent sensitivity of the ganglion cell to caffeine, when it was impaled with a K_3-citrate electrode.

Table 1 Effects of various anions in a recording electrode on the appearance of slow rhythmic hyperpolarisations at different caffeine concentrations

	Caffeine (mM)		
		0.5	1.0
K_3-citrate (1.0 M)	21/23 (91%)	25/25 (100%)	—
K-acetate (3.0 M)	11/16 (69)	14/18 (78)	18/18 (100%)
K_2-sulphate (0.3 M)	8/12 (67)	11/15 (73)	15/15 (100)
KCl (3.0 M)	4/18 (23)	11/22 (50)	22/22 (100)

Numerators are the number of cells in which rhythmic hyperpolarisations were observed, and denominators are the number of cells examined. In the experiments using electrodes filled with K-acetate, K_2-sulphate and KCl, the cells which showed rhythmic hyperpolarisations at a caffeine concentration of 3 mM were studied. When caffeine was absent rhythmic hyperpolarisations were recorded only in the cells which were penetrated with an electrode filled with 1 M K_3-citrate.

The ability of various anions to generate slow oscillatory hyperpolarisations was tested by penetrating a cell with an electrode filled with K-salts of various anions, and observing for each electrode the number of the cells which exhibited slow oscillatory hyperpolarisations at a given concentration of caffeine (Table 1). The order of favourable anions was citrate > acetate and/or > sulphate > Cl.

There may be several interpretations for this order. First, assuming that both A- and C-hyperpolarisations are generated by the intracellular release and uptake cycle of Ca^{2+} at a Ca^{2+} storage site[11], this order of anions may indicate their ability to release Ca^{2+} from the storage site like caffeine; citrate would be most effective, and Cl^- would have no effect. The latter case would thus require caffeine. Second, the order of these anions may reflect depressant actions on the Ca^{2+} release mechanism in the ganglion cell. Endo[16] reported that a sustained treatment of the SR with a low concentration of Cl^- inactivated the release of Ca^{2+}. As the Ca^{2+} storage site in the ganglion cell seems to resemble the SR in its properties[11,13], Cl^- leaked out of an electrode into the cytoplasm may depress the Ca^{2+} release mechanism in the ganglion cell. This Cl^- action may be antagonised by caffeine. If so, citrate may be inert and A-hyperpolarisations could be a physiological phenomenon. We do not yet know which of these possibilities is operative. In any case, it is quite clear that the species of intracellular anions in the ganglion cell markedly affects the mechanism of the slow oscillatory hyperpolarisations.

It is unlikely that the present findings are the result of a chelating action of citrate because the estimated intracellular concentration of citrate was not high enough to produce a chelating action, and because such a chelating action would have blocked A-hyperpolarisations[11,13,14].

Glucocorticosteroids modulate transmitter choice in developing superior cervical ganglion

I. S. McLennan, C. E. Hill & I. A. Hendry

Department of Pharmacology, John Curtin School of Medical Research,
Australian National University, PO Box 334, Canberra, ACT 2601,
Australia

***In vivo* the superior cervical ganglion (SCG) is adrenergic with less than 5% of neurones expressing cholinergic properties[1]. *In vitro* these neurones can develop either an adrenergic or cholinergic phenotype, depending on the nature of the culture conditions[2]: when immature SCG neurones are cultured in the virtual absence of non-neuronal cells they develop adrenergic properties, synthesising noradrenaline (NA) and a negligible amount of acetylcholine (ACh)[3,4]; when ganglionic non-neuronal cells are present the neurones develop a cholinergic phenotype, characterised by increased ACh synthesis and a corresponding decrease in NA synthesis[5]. If ganglionic non-neuronal cells release a factor which induces cholinergic properties *in vitro*, why is the SCG not cholinergic *in vivo*? *In vitro* there are none of the presynaptic, postsynaptic, or circulatory hormonal influences normally present in neuronal development. Depolarisation of SCG neurones *in vitro* prevents the development of cholinergic properties, suggesting that the preganglionic input *in vivo* may maintain the adrenergic nature of the SCG[6]. However, as prevention of depolarisation of neurones *in vivo* by preganglionic nerve section does not alter the adrenergic character of the SCG, influences other than the preganglionic input must be involved in preventing the development of cholinergic properties *in vivo*[7]. Circulatory glucocorticosteroids modulate the induction of neurotransmitter synthetic enzymes in the SCG[8,9] and have been reported to change the expression of adrenergic and cholinergic properties in a pheochromocytoma cell line[10]. We present here results suggesting that glucocorticosteroids are involved in specifying the transmitter type used in the SCG.**

SCG from 3-day-old rats were cultured on collagen-coated plastic multitrays (Linbro 76-033-05) in Dulbecco modified Eagle's medium containing 50 mM HEPES, 100 U ml^{-1} penicillin G, 10% inactivated horse serum, 1 μg ml^{-1} β-nerve growth factor (βNGF) and varying concentrations of dexamethasone (DXM) or corticosterone. After 14 days incubation choline acetyltransferase (CAT) and tyrosine hydroxylase (TH) activity were determined by previously described methods[12,13].

DXM antagonised the conversion of the SCG from an adrenergic to a cholinergic phenotype *in vitro*, resulting in a dose-related increase in the activity of TH and a corresponding decrease in CAT activity (Fig. 1*a*). The CAT:TH ratio, a sensitive measure of the degree of cholinergic character, decreased with increasing DXM concentration, reaching a minimum at 10^{-7} M DXM (Fig. 1*b*).

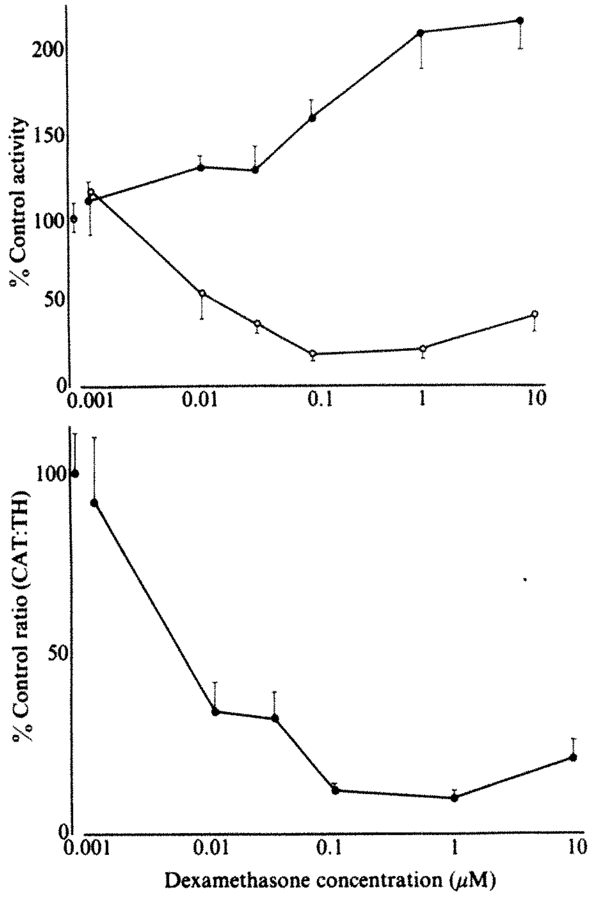

Fig. 1 Effect of dexamethasone on enzyme activities in cultured superior cervical ganglia. *a*, Effect on tyrosine hydroxylase (●) and choline acetyltransferase (○) levels; *b*, effect on the ratio of choline acetyltransferase to tyrosine hydroxylase activity. Activities are expressed as a percentage of the activity of control ganglia grown in the absence of dexamethasone. Control values were TH: 62 ± 5 pmol h^{-1} per ganglion; CAT: 0.76 ± 0.07 nmol h^{-1} per ganglion and CAT:TH 12.2 ± 1.3. Points are means ±s.e.m. for 12, 6, 6, 12, 12, 12, 12 ganglia respectively. All ganglia were cultured for 14 days and the medium was changed every 4 days.

Table 1 Effect of glucocorticoids on the ratio of choline acetyltransferase (CAT) to tyrosine hydroxylase (TH) in cultured rat superior cervical ganglia and comparison with the intrinsic ratio *in vivo*

	CAT:TH
In vitro	
Control	13.6 ± 1.8
Dexamethasone 10^{-7} M	1.0 ± 0.2
Corticosterone 10^{-6} M	0.5 ± 0.1
Corticosterone 10^{-5} M	0.0 ± 0.2
In vivo	
Decentralised	0.6 ± 0.1

Superior cervical ganglia from 3-day-old rat pups were decentralised or placed in culture and the activity of TH and CAT determined 14 days later. Ratios are means ±s.e.m. for six ganglia.

The naturally occurring glucocorticosteroid in rats is corticosterone. At the physiological plasma level for neonatal rats (1 μM)[14], this steroid was similar to DXM in its ability to alter the levels of CAT and TH. The ratio of CAT:TH in these cultures is comparable to the CAT:TH ratio observed in decentralised ganglia *in vivo* (Table 1).

These results indicate that physiological levels of glucocorticosteroids can influence the choice of transmitter type of the developing SCG *in vitro*. The glucocorticosteroids may be acting on (1) the non-neuronal cells to cause either a decrease in the production or liberation of a factor inducing cholinergic properties, (2) directly on the neurones to alter their responsiveness to such a factor or (3) selective destruction of cholinergic neurones. Irrespective of whether glucocorticosteroids act directly or indirectly on neurones it is likely that during the development of the SCG *in vivo* circulating levels of corticosterone are in part responsible for the adrenergic phenotype of the ganglion, despite the presence of non-neuronal cells which *in vitro* cause the SCG to become primarily cholinergic.

Compact myelin exists in the absence of basic protein in the shiverer mutant mouse

Street, Boston, Massachusetts 02115

The myelin sheath is a multilamellar membrane system which surrounds axons in vertebrates and provides the electrical insulation necessary for saltatory nerve impulse conduction. Myelin forms from its cell of origin as a flattened, membrane-bound cytoplasmic process which wraps spirally around the axon; a periodic compact array of membrane pairs is produced from the wrappings as the cytoplasmic contents are extruded, and the external surfaces of membranes become apposed[1,2]. Neurological mutant mice which show myelin abnormalities are useful models for examining the formation, stability and breakdown of myelin. For example, the shiverer mouse carries an autosomal recessive mutation[3] (*shi*)[4] that results in severe myelin deficiency in the central nervous system (CNS)[5,6], apparently due to a defect in myelin formation[5,6]. The small amount of myelin that does form in the CNS is generally not compacted at its cytoplasmic surfaces[6], possibly due to the low level of basic protein in shiverer CNS tissue[7]. In the peripheral nervous system (PNS), in contrast, amounts of compact myelin seem to be normal[6]. The coarse tremor and convulsions that begin at about 2 weeks of age in the shiverer are presumably due to the severe CNS deficiency of myelin, as similar neurological signs are shown by other mutants with reduced CNS myelin[8]. Most studies on such mutants have concentrated on those regions of the nervous system which are grossly deficient in myelin[5–10]. In the other regions myelin seems by light microscopy to be normal. At the ultrastructural and molecular level, however, this myelin sometimes shows abnormalities[11–14], and this has prompted us to examine intensively such myelin in several neurological mutants. For this we have used X-ray diffraction, electron microscopy and SDS-polyacrylamide gel electrophoresis (SDS-PAGE). We report here that, of the mutants we have examined so far, the shiverer mouse is unique in showing a striking alteration in myelin protein composition that does not significantly affect the gross morphology and lamellar organisation of the myelin sheath. Our results thus question the proposed role of basic proteins[15–19] in myelin as 'structural cement'.

X-ray diffraction patterns of myelin were obtained from freshly dissected sciatic nerves of adult normal and shiverer mice (Fig. 1*a*). The patterns extend to 0.06 Å^{-1} and are similar in their fundamental spacings and in the relative intensities of the reflections; this indicates that the packing and molecular organisation of the membranes in myelin from the shiverer mouse correspond closely to that from the normal mouse. The patterns also show comparable linewidths and total integrated intensities for the reflections, which means that the regularity of the packing of the membrane pairs in myelin and the total amount of myelin are similar in both animals. Small differences between the patterns, however, were consistently observed. Measurement of the normalised diffraction intensities shows that the first, fourth, sixth and eighth order reflections are increased and that the third and fifth orders are decreased in shiverer compared with the normal. These differences reveal an alteration in membrane bilayer structure of shiverer peripheral nerve myelin. Electron density profiles (Fig. 1*b*) calculated from the diffraction data show that in shiverer myelin there is a significant decrease in electron density on the cytoplasmic side of the bilayer both in the space between bilayers and at the position of the lipid polar head groups. Definitive assignment of these changes in electron density to particular molecular constituents requires chemical characterisation of shiverer peripheral nerve myelin.

Electron micrographs of adult shiverer mouse sciatic nerve show that the myelin is abundantly present as normally compact arrays of membrane pairs (Fig. 2). High magnification electron micrographs of shiverer myelin reveal typical major dense lines and double intraperiod lines which represent, respectively, the appositions of membranes at their cytoplasmic and at their extracellular surfaces. These results confirm the conclusions drawn from the X-ray diffraction measurements that the relative amounts of myelin and the regularity of membrane packing in normal and shiverer mice are similar. Moreover, electron micrographs of shiverer sciatic nerve do not reveal any obvious signs of myelin breakdown such as Schwann cell lysosomes filled with myelin debris or macrophage phagocytosis of the sheath.

The protein composition of myelin in normal and shiverer nerves was analysed with SDS-PAGE. Whole sciatic nerves were dissolved in SDS and electrophoresed in SDS on polyacrylamide gradient slab gels using the discontinuous buffer system of Maizel[20]. The myelin protein bands were identified by co-electrophoresing isolated myelin from normal mouse sciatic nerve and purified myelin proteins. Before examining the shiverer mutant, which is on a hybrid background in our laboratory, we compared the electrophoretic patterns of sciatic nerve proteins from six strains of normal mice (C57BL/6J, DBA/2J, BALB/CWt, C3H/HeJ, CBA/J and AKR/J). The patterns were virtually identical. Therefore, the hybrid background of shiverer would not be expected to produce any variations that might be seen in the banding patterns—variations would be attributable to the mutation.

The gel of normal and shiverer sciatic nerves from animals of different ages (Fig. 3) shows that the major myelin protein, P_0 glycoprotein[21], is present in comparable amounts at all ages. In contrast, the myelin basic proteins P_1 and P_2 (ref. 21) are present in normal but are absent from shiverer nerves. We also note small differences between shiverer and normal among certain minor protein bands of myelin. We are now examining whether the basic proteins are present transiently in shiverer before 2 weeks of age, during the earliest stages of myelin formation. We have also found that the basic proteins were undetected in adult shiverer sciatic nerve even after loading the gel with twice the usual amount. In trigeminal nerve of the shiverer mouse a similar absence of myelin basic proteins was found. The fact that no additional bands appear in the shiverer gels means that no other proteins are produced which could replace the basic proteins, with the possible exception of small peptides that could pass through the 18% acrylamide portion of the gel and be undetected.

The apparent lack of myelin basic proteins in peripheral nerves of the shiverer mouse might be explained by selective proteolytic activity during preparation for SDS-PAGE. We tested this possibility by three separate procedures. (1) Shiverer sciatic nerves were boiled for 2 min in 2% SDS immediately after dissection to denature proteases. (2) Shiverer sciatic nerves

0028-0836/80/020207—04$01.00

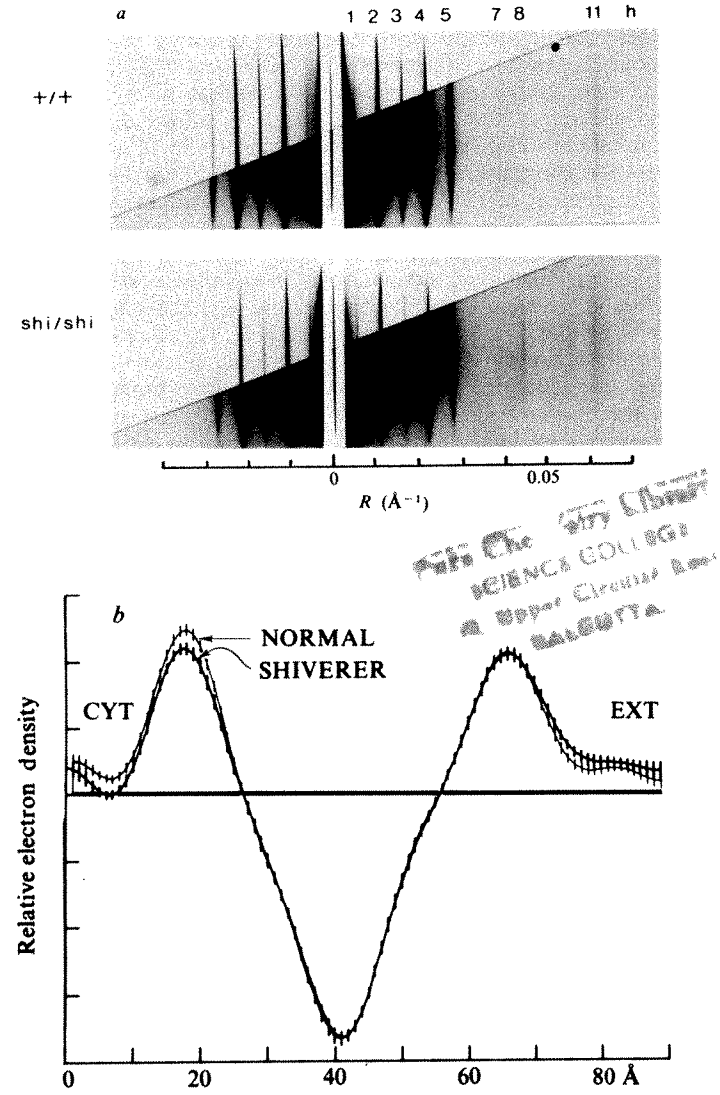

Fig. 1 X-ray diffraction from sciatic nerves of normal (+/+) and shiverer (*shi/shi*) mice. *a*, Diffraction patterns were obtained at room temperature from nerves mounted under tension in thin-walled quartz capillaries containing phosphate-buffered saline (0.9% NaCl, 0.01 M sodium phosphate, *p*H 7.4). The X-ray source was a fine-line Philips X-ray tube operated at 40 kV, 15 mA. Linear collimation and monochromatisation for CuKα radiation was achieved using a bent nickel-coated optical flat. The X-ray camera had a specimen-to-film distance of 200 mm. Exposure times were 12–20 h using Ilford Industrial G film. Top films and underfilms are presented to show both the strong, low order reflections and the weak, higher orders. The reciprocal space coordinate, R, is indicated along the bottom and the Bragg or diffraction orders, h, are numbered along the top. Both diffraction patterns show strong, even orders and weak, odd orders for $R < 0.03$ Å^{-1} and show weak, discrete reflections to $R \approx 0.06$ Å^{-1}. The most obvious differences between the patterns are the decreased intensities of the third and fifth orders, and the increased intensity of the first order in the shiverer. The spacings and optical densities of the diffraction orders were measured by a Joyce-Loebl MK III C microdensitometer. The repeat period measured for normal sciatic nerve myelin is 177 Å and for shiverer it is 178 Å; the 1-Å difference is less than the variability among different specimens. Measurements of the diffracted intensities were made on sciatic nerves from six normal and two shiverer mice. Integrated peak intensities, $I(h)$, were determined by planimetry after background subtraction using a Numonics digitiser interfaced to a PDP 11/05 computer. Structure amplitudes, $F(h)$, were calculated from $(hI(h))^{1/2}$ and were normalised so that $\sum_h F^2(h)/d = \text{constant}$[37]. The final sets of amplitudes that were used to derive the electron density profiles for the normal and shiverer myelin membranes were obtained by calculating a weighted average of the amplitudes for each diffraction order h. Individual standard deviations of the structure amplitudes were used as the weighting factors. These standard deviations arise from determining peak intensity over background, comparing the integrated intensity from corresponding peaks on either side of the direct beam, and scaling the weak and strong reflections recorded on different films during an exposure. The mean uncertainty of the measurements, calculated from the sum of the standard deviations of the amplitudes divided by the sum of the amplitudes, was about 6%. *b*, Electron density profiles of the myelin membranes were calculated from the structure amplitudes, $F(h)$, with phases assigned as previously described[12,38]. The profiles are plotted from the centres of the cytoplasmic fluid spaces (cyt) and extend to the centres of the extracellular fluid spaces (ext) between membrane bilayers; this represents half the membrane pair which constitutes the repeating unit of myelin. The short vertical bars on the density profiles show an uncertainty of 1 s.d. from the mean value of the profile[12]. The profiles were superposed to minimise the differences between the membrane bilayers. Overall, the membranes have similar electron density distributions. However, the shiverer myelin membrane does show a significant decrease in electron density at the polar head group region on the cytoplasmic half of the lipid bilayer. This could be accounted for by a loss of electron dense protein and/or of lipid polar groups. There is also in shiverer myelin a decrease of the average electron density in the cytoplasmic space which might be due to a local decrease in protein concentration.

were homogenised in 2% SDS containing three protease inhibitors (10^{-5} M leupeptin[22], 10^{-4} M *o*-phenanthroline[23], 10^{-3} M phenylmethyl sulphonyl fluoride[24]; Sigma). (3) The sciatic nerves of normal and shiverer mice were homogenised together in 2% SDS; in this mixture myelin basic proteins present in normal nerve would be exposed to any protease in shiverer nerve. Boiling or the use of protease inhibitors had no effect on the gel pattern of shiverer sciatic nerve. Mixing of shiverer nerve with the normal nerve did not alter the amount of basic proteins expected from the normal. We conclude that proteolytic activity does not explain the absence of basic proteins in shiverer peripheral nerve myelin.

Radioimmunoassay (RIA) provides a second, more sensitive method for detecting myelin basic proteins. A quantitative comparison of the levels of P_1 basic protein in normal and shiverer sciatic nerves was made (Table 1); inclusion of the detergent cetyltrimethylammonium bromide in the RIA buffer[25] ensured full expression of this protein. The value for the amount of P_1 basic protein in shiverer, using 1% nerve homogenates, is at the background level of the assay. This indicates at least a 200-fold reduction of basic protein in shiverer relative to normal. Determination of the absolute amount of P_1 basic protein in shiverer would depend on using more concentrated nerve homogenates. Failure to detect this protein in shiverer nerve might be due to inhibition of the antigen–antibody reaction in the RIA by some factor endogenous to shiverer nerves. We tested this possibility by carrying out the assay on a one-to-one mixture of normal and shiverer nerve homogenates. The level of P_1 basic protein measured was half the amount in normal nerve that would be expected if there were no interference with the antigen–antibody reaction. The RIA also indicates that immunoreactive fragments of P_1 basic protein are not present in shiverer nerve. We intend to quantitate the parallel lack of P_2 basic protein from shiverer peripheral nerves using RIA.

We have found that shiverer peripheral nerve myelin lacks basic proteins but that the lamellar arrangement of membranes—the repeat period and the widths of the cytoplasmic and extracellular spaces—are the same as in normal myelin. At the level of the individual myelin membrane bilayers, however, we find a small decrease in electron density of the polar head group region in the cytoplasmic half of the bilayer, which could be accounted for by the absence of basic proteins from that region. This decrease might also be explained by a reduced proportion of phosphate-containing lipids, a possibility that is now being examined.

Table 1 Radioimmunoassay of P_1 basic protein in mouse sciatic nerve

	µg P_1 per mg wet weight
Normal	4.05±0.46
Shiverer	0.019±0.015

1% (w/v) homogenates of sciatic nerves were made in RIA buffer containing 0.2 M Tris-acetate (*p*H 7.3), 1% cetyltrimethylammonium bromide, 1 mg ml^{-1} calf thymus histone, 0.5% (w/v) calf serum and 0.02% sodium azide. The homogenates were centrifuged to remove connective tissue and 10-µl aliquots of the supernatants, diluted 1 : 100 with RIA buffer for the normal and undiluted for the shiverer, were used for the assay. The values given represent the averages of assays on the sciatic nerves from each of three different normal and three different shiverer mice. The RIA was carried out as described by Cohen[25] and detects both A_1 and P_1 basic proteins.

The proposed role of basic proteins as 'structural cement' in myelin compaction and stabilisation[15-19] derives from the physicochemical properties of basic protein from the CNS, where it accounts for 25–50% of the total protein of isolated myelin[15]. Because it is an extrinsic membrane protein, that is, easily extracted by dilute acid or salt solutions[26], it is most probably localised to membrane surfaces. Large basic protein (named A_1 in CNS myelin) is highly cationic at physiological *p*H, with an isoelectric point of 10.5 (ref. 27) or 12–13 (ref. 28), and will complex with acidic lipids[29], with which it forms lamellar systems[30]. CNS basic protein is also able to interact hydrophobically with lipids[31], presumably due to the nonpolar regions in the protein molecule[32]. The basic proteins of PNS myelin have similar properties[15,30,31,33,34] and a similar structural role has therefore been suggested for them[17]. However, the lower amounts of basic proteins in PNS myelins, which range from 22% of total myelin protein in rabbit sciatic to as little as 6% in rat sciatic nerve[35], lead one to question such a structural role for basic proteins in the PNS. Moreover, the virtual absence of basic proteins from shiverer peripheral nerve myelin demonstrates that these proteins are not required to maintain stable, compact myelin in the PNS. Possibly, the function of structural cement in peripheral nerve myelin is provided by P_0 glycoprotein, which constitutes 50–65% of the total myelin protein[35]. In contrast, if CNS myelin does require basic protein as a structural component, the absence of this protein as a result of the shiverer mutation[7] would explain the defective myelin formation of the CNS[5,6]. A preliminary account of this work has been reported elsewhere[36].

We thank Professor R. L. Sidman for valuable discussions and encouragement, Dr J. Cowan and Mr M. Baker for providing the shiverer mice, Dr S. R. Cohen for carrying out the RIA,

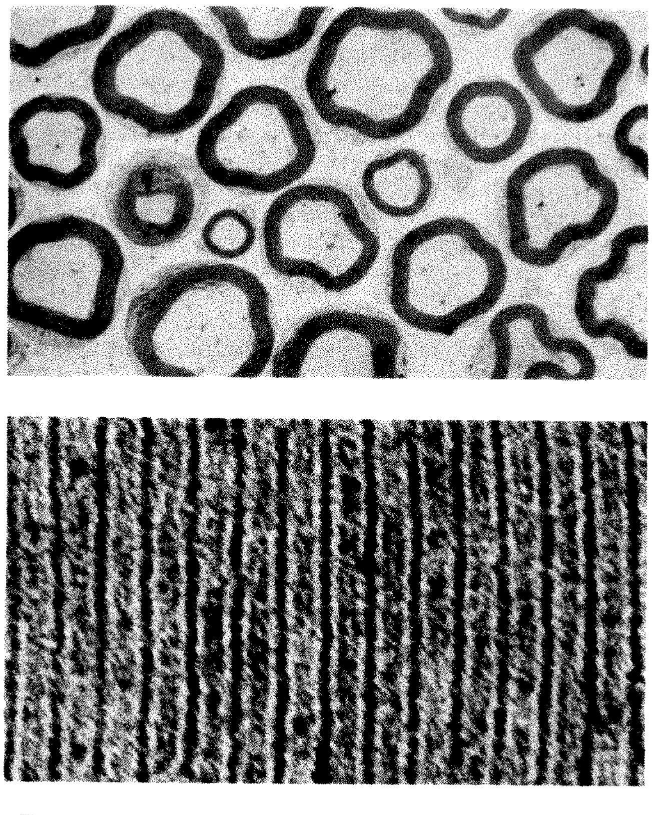

Fig. 2 Electron micrographs from shiverer sciatic nerve. Upper: low magnification view (×2,400) shows nerve fibres that seem to be normally myelinated. Lower: at high magnification (×434,000) the major dense lines and the double intraperiod lines of the array of myelin membranes are apparent. Continuity of the intraperiod lines can be seen more clearly by viewing the micrograph obliquely. Nerves were fixed with glutaraldehyde, postfixed with ferrocyanide-OsO_4, *en bloc* stained with uranyl acetate, dehydrated in methanol: methyl Cellosolve (1:1) and embedded in Epon; thin sections were counterstained with uranyl and lead.

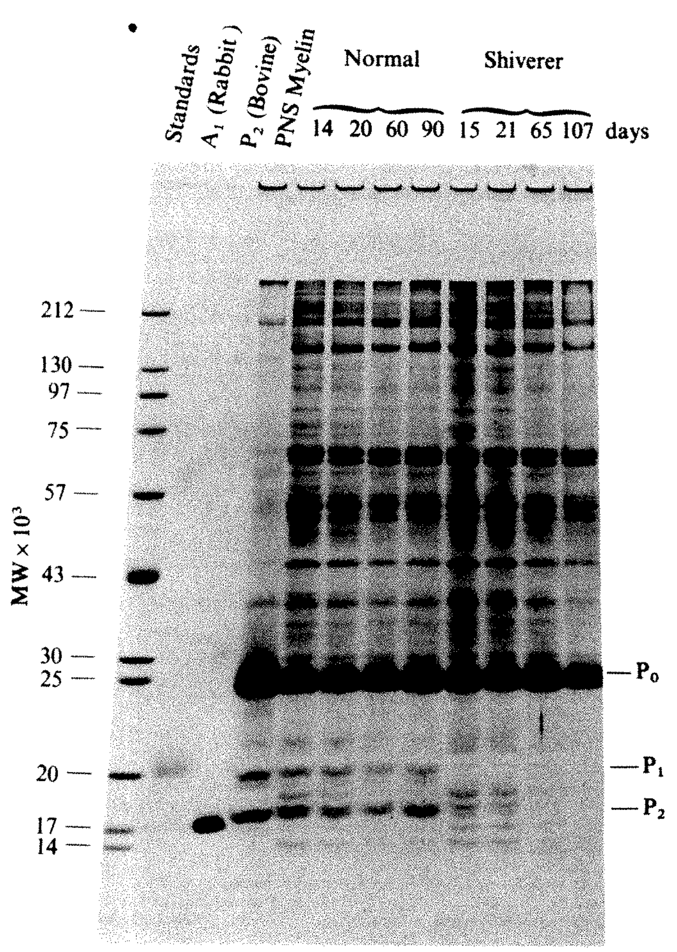

Fig. 3 SDS-PAGE analysis of protein composition of normal and shiverer sciatic nerves from animals of different ages. Nerve homogenates (15 mg wet weight per ml) were prepared in 2% SDS at room temperature, then diluted 1:1 with a mixture of 20 mM Tris-phosphate buffer at *p*H 6.7, 10% β-mercaptoethanol, 20% Ficoll and 0.002% bromphenol blue and finally stored frozen until electrophoresis. The electrophoretic system of Maizel[20] was used with the exceptions that the resolving gel was a slab 0.75 mm thick and 12 cm long, with an 8–18% gradient of acrylamide, and the stacking gel was 4% and made up in 62.5 mM Tris-phosphate at *p*H 6.7. Sample aliquots of 20 μl per lane were electrophoresed at room temperature at a constant voltage of 40 V for 2 h, which brought the dye front into the resolving gel, and then 180 V for 4.5 h. The gels were fixed overnight in 50% methanol–10% acetic acid and subsequently stained for 1 h with 0.1% Coomassie Brilliant Blue R in 50% methanol–10% acetic acid. After destaining in 10% methanol–10% acetic acid the gels were photographed through a yellow filter (Kodak K 2). The molecular weight (MW) standards are: myosin at 212,000, β-galactosidase at 130,000, phosphorylase *a* at 97,000, conalbumin at 75,000, pyruvate kinase at 57,000, ovalbumin at 43,000, carbonic anhydrase at 30,000, chymotrypsinogen A at 25,000, soybean trypsin inhibitor at 20,000, myoglobin at 17,000, and lysozyme at 14,000. Myelin basic protein A_1, prepared from rabbit brain[39], is quite similar to P_1 basic protein of PNS[33]. Myelin basic protein P_2 was prepared from bovine intradural spinal roots[40]. PNS myelin was purified[41] from sciatic nerves of normal C57BL/6J mice. The major myelin proteins[21] of the sciatic nerve homogenates, P_0 glycoprotein and P_1 and P_2 basic proteins, are identified by comparison with the electrophoretic banding patterns of purified myelin basic proteins from other species and of myelin isolated from mouse sciatic nerves. P_1 and P_2 migrate in this gel system at the apparent MWs of ~20,000 and ~18,000; the actual MWs calculated from amino acid analysis of rabbit P_1 is 18,000 (ref. 21) and of bovine P_2 is 14,300 (ref. 42). Of the myelin proteins, P_0 glycoprotein is prominent in the gels of normal and shiverer mice, whereas P_1 and P_2 basic proteins are not visible in the shiverer. Two- and three-week-old normal and shiverer mice show more bands in the low MW region of the gels than do the adults. Two of these bands border the P_2 protein and are more apparent in shiverer because of the absence of this basic protein. They are, however, present in gels of normal nerves, especially at 14 days. Apart from the myelin proteins, the banding patterns at corresponding ages are virtually identical.

Mr W. G. Busse for photographic services, and Drs S. Margossian, M. W. Kies and K. Uyemura for various MW standards. The research was supported by NIH-NINCDS NS 14326 to D.A.K. and the neurological mutant mouse colony was supported by NIH-NINCDS 5 R01 NS 11237 to R. L. Sidman. The work was carried out in facilities related to the Mental Retardation Research Center at the Children's Hospital Medical Center and was supported by NIH Core grant HD 06276.

Evolution and gene transfer in purple photosynthetic bacteria

Richard E. Dickerson

Norman W. Church Laboratory of Chemical Biology, California Institute of Technology, Pasadena, California 91125

A concern voiced in connection with recent sequencing of cytochrome *c* from the Rhodospirillaceae or purple non-sulphur photosynthetic bacteria[1-3] is that molecular information might be of little use in deciphering bacterial phylogeny because of the possibility of lateral transfer of genes and the consequent scrambling of the genetic record. This could be true for many proteins, of course, but the immediate question is, is it true for cytochromes *c*, for which extensive primary sequence[1-3] and X-ray structure[4-10] information is available for comparison? The evidence suggests that this is probably not so. The disagreement between cytochrome *c* sequences and the standard taxonomy of the Rhodospirillaceae in Bergey's Manual[11] is not a problem. That reference, as its title indicates, is a manual of determinative rather than evolutionary bacteriology. Its goal is a reproducible system for identification of bacteria. If one claims that these determinative categories also have phylogenetic or evolutionary meaning, this is an assertion that must be proven. The argument outlined below suggests that molecular traits may eventually become more a dependable basis for classification of the Rhodospirillaceae than is gross morphology.

Table 1 contains information rearranged from Table 1 of Ambler *et al.*[1], with the addition of two more species, and with further information about the positions of chain insertions in the cytochromes *c* and sequence comparisons between the 16S RNA subunits of bacterial ribosomes. The ribosomal RNA classification is discussed in greater detail in the following paper[12], and more detailed information on cell shape and infolding of the photosynthetic membrane may be found in Pfennig and Trüper[13]. X-ray crystal structure analyses reveal that the cytochromes c_2 and c_{551} from the Rhodospirillaceae fall naturally into three structural classes, each of which has a parallel among purely respiratory cytochromes c_{551}, *c* or c_{550}. These structural classes are shown in Fig. 1. The short (or S) cytochromes c_{551} from *Rhodopseudomonas gelatinosa* and *Rhodospirillum tenue* resemble, in both sequence and folding, the respiratory c_{551} from pseudomonads and *Azotobacter* (Fig. 1*a*). Cytochromes *c* of the medium or 'mitochondrial' (M) class are similar in length and sequence to cytochrome *c* from eukaryotic mitochondria, and all have the extra chain at the bottom of the molecule that is shaded and marked by I in Fig. 1*b*. Others, the long or L class, resemble *Paracoccus* c_{550} by having the shaded insertions marked II and III in Fig. 1*c*, and sometimes insertion IV as well. Moreover, the inserted amino acids in these photosynthetic and respiratory cytochromes *c* are similar in sequence, arguing for a common evolutionary origin. All these molecules—*c*, c_2, c_{550}, c_{551} and c_{555} (from *Chlorobium*)—seem to make up one large evolutionarily related family of proteins. The presence or absence of chain insertions I, II, III and IV is listed as one of the traits in Table 1.

In Table 2, the amino acid sequences of cytochrome c_2 or c_{551} from the Rhodospirillaceae are compared quantitatively in two different ways. Below the matrix diagonal, which contains the total number of amino acids in each protein, are tabulated the number of identical positions in pairwise comparisons of sequences. The number of differences between sequences is found above the diagonal. (As is customary, a deletion in one chain but not the other is included in the tally of differences.) For closely related sequences, the difference matrix is best for showing changes in sequence, but for more distantly related sequences such as these, the identities matrix is better. It avoids the difficult question of whether to treat a long chain deletion as one evolutionary event or many, and provides a measure of how nearly identical two sequences are in those regions of chain that they have in common. Gross insertions or deletions in the chain (such as regions I–IV) can then be assessed separately.

If the information in Tables 1 and 2 is arranged by Bergey genera, the principal impression is one of confusion. However, if the Bergey genera are set aside, a strong correlation can be seen between the size and sequence of cytochromes *c*, type of infolding of outer bacterial membrane, and 16S ribosomal RNA sequences. Those species that have class II RNA sequences also have short cytochromes *c* and tubular membrane infoldings, even though they fall into three different Bergey genera. (The amino acid sequence of *Rhodocyclus purpureus* cytochrome is not known, but one would predict that it is a short cytochrome.) Both the identity and the difference data in Table 2 show that the S cytochromes *c* are very different in sequences from the M and L (a mean and mean deviation of 16.4 ± 2.2 identities between S and M or L). The M and L classes are more nearly alike, but there are fewer identities between M and L (38.6 ± 3.3 identities) than between different M (50.3 ± 8.3) or L (49.4 ± 6.1). The presence or absence of insertions II, III and IV, of course, draws a clear distinction between M and L cytochromes.

Abbreviations: *R.*, *Rhodospirillum*; *Rps.*, *Rhodopseudomonas*; *Rm.*, *Rhodomicrobium*; *Rcy.*, *Rhodocyclus*. S, M, L: short, medium and long cytochromes *c* as described in the text.

* Possess.two similar isozymes of c_2.

Rps. gelatinosa, *R. tenue* and *Rcy. purpureus* show a diversity of cell shapes, which led to their assignment to different genera in the original Bergey classification. If one accepts this separation, and argues that these three species show common cytochrome properties because of lateral gene transfer, one must not only assume that the genes for cytochromes *c* and for photosynthetic membrane configuration are closely linked and jointly transferrable, but that they are both also linked to the genes responsible for the 16S RNA components of their ribosomes. At this point, gross morphology begins to look like the weakest of the available traits for phylogenetic classification.

Those species with M or L cytochromes *c* all have class I ribosomal RNA sequences. Their cell membrane infoldings are vesicles or stacked lamellae, never tubules. The cells reproduce either by simple binary fission, or in four species by asymmetric budding. The limited information in Tables 1 and 2 does not provide a clear basis for subgroupings. One should keep an open mind on the subject until more information is available, perhaps from sequences and structures of proteins that are quite different from the cytochromes. However, Table 2 does indicate close affinities between ***Rhodopseudomonas sphaeroides*** and ***Rhodopseudomonas capsulata***, between ***Rhodospirillum rubrum***

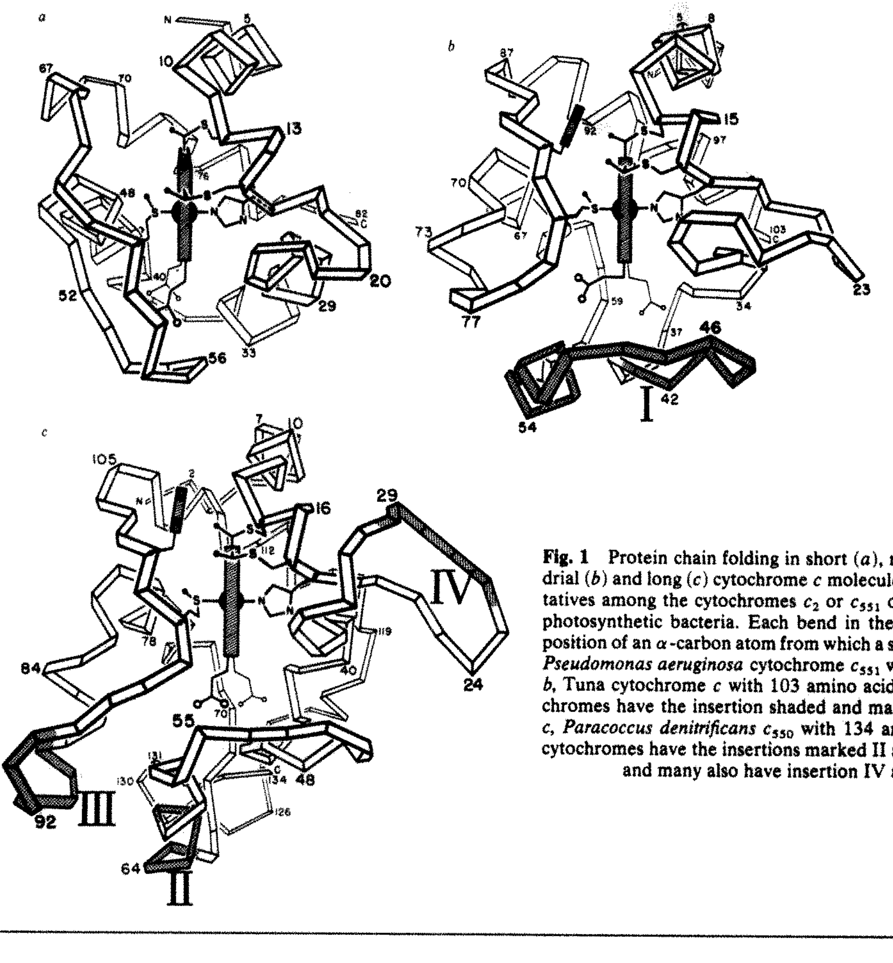

Fig. 1 Protein chain folding in short (*a*), medium or mitochondrial (*b*) and long (*c*) cytochrome *c* molecules. All have representatives among the cytochromes c_2 or c_{551} of purple non-sulphur photosynthetic bacteria. Each bend in the ribbon indicates the position of an α-carbon atom from which a side chain branches. *a*, *Pseudomonas aeruginosa* cytochrome c_{551} with 82 amino acids[10]. *b*, Tuna cytochrome *c* with 103 amino acids[8]. All medium cytochromes have the insertion shaded and marked I at the bottom. *c*, *Paracoccus denitrificans* c_{550} with 134 amino acids[6]. All long cytochromes have the insertions marked II and III at the bottom, and many also have insertion IV at the right.

Table 2 Pairwise sequence comparisons of cytochromes *c*

Italic numbers on the diagonal give the length of each chain. Below diagonal: total number of identical positions. Above diagonal: total number of differences. Sequences lettered at top as at far left.

and *Rhodospirillum photometricum*, between three and possibly the fourth budding species, and between *Rhodospirillum molischianum* and *Rhodospirillum fulvum*, all of which are reasonable on other grounds. We have very tentatively drawn the phylogenetic tree shown in Fig. 2 as the basis for future discussion of new data. It suggests a point that we believe to be quite important, and which was first enunciated by Broda[14,15]: the polyphyletic origin of respiring bacteria from more than one line of photosynthetic ancestors.

It may be that lateral gene transfer and blurring of the evolutionary record will be a serious problem for some proteins, especially those that are intrinsically useful to a bacterium in their own right, without an attendant metabolic setting. However, with the proper choice of proteins this difficulty should be capable of being overcome, and the cytochrome *c* record provides grounds for optimism.

This work was supported by NSF grant PCM77-15335 and NIH grant GM-12121.

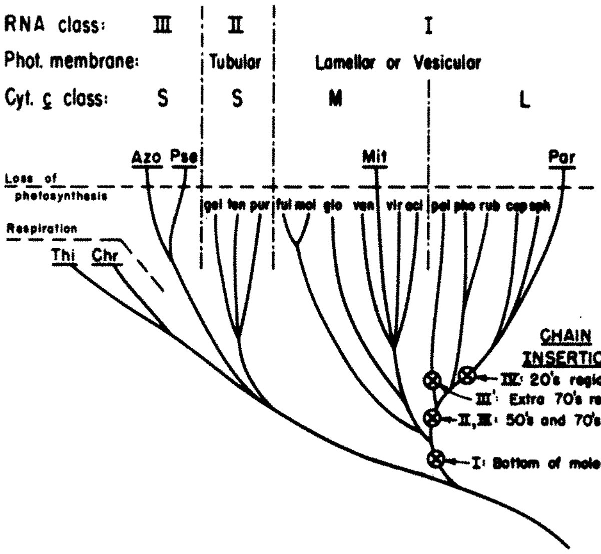

Fig. 2 Tentative phylogenetic tree of the purple photobacteria, based on the metabolic, morphological, protein and RNA data presented in Tables 1 and 2. The original cytochrome *c* is assumed to have been small, like *Chlorobium* c_{555} and *Anacystis* c_{554}. Circled crosses mark the four places where specific insertions of polypeptide chain are presumed to have occurred. Do genealogical patterns in purple photosynthetic bacteria reflect interspecific gene transfer?

Carl R. Woese*, Jane Gibson† & George E. Fox‡

It is generally thought that interspecific (lateral) transfer of genes is so extensive among bacteria that it is difficult, and perhaps impossible, to determine their phylogenetic relationships. Ambler and coworkers[1] reflect this in their suggestion that the relationships seen among cytochrome *c* sequences of the Rhodospirillaceae are merely the result of a haphazard lateral transfer of the particular gene, and give no indication of the true bacterial phylogenies. However, if comparative analysis of several unrelated macromolecules yields essentially the same phylogenetic tree, then that pattern is extremely unlikely to reflect the lateral transfer of genes[2]. We have also determined 16S ribosomal RNA catalogues[3] for many of the Rhodospirillaceae investigated by Ambler *et al.* and here we use these two sets of data to compare molecular phylogenies for these bacteria.

0028-0836/80/020212—03$01.00

The conclusion of Ambler *et al.*[1], suggesting that the relationships seen among cytochrome *c* sequences of the Rhodospirillaceae are merely due to random lateral transfer of the relevant gene, is based on three arguments. First, within the purple photosynthetic bacteria there is 'no correlation between a species' cytochrome *c* amino acid sequence and its phylogenetic position'; second, the cytochromes *c* from some of the Rhodospirillaceae seem to be more closely related to those from certain nonphotosynthetic organisms, for example pseudomonads, than they are to those from other members of the Rhodospirillaceae; and third, three different proteins—cytochrome c_{551}, cytochrome c', and the high potential iron sulphur protein—seem to produce three dissimilar phylogenetic trees for the same (small) set of organisms[1,4]. The first two arguments assume that we already know the true phylogeny for the Rhodospirillaceae, which is not the case. The genera now defined for the purple photosynthetic bacteria are not intended to be phylogenetic categories[5,6]; generally agreed phylogenetic categories for these organisms have never been proposed. In addition, the second argument seems to reflect the idea that the photosynthetic bacteria must be phylogenetically quite distinct from nonphotosynthetic bacteria (with perhaps a few exceptions). Although this view is widely accepted[7,8], it has no factual support.

Our objection to the lateral transfer explanation is not based primarily on counter-argument, however, but on the facts available. If a phylogeny derived from a comparative analysis of one macromolecular species reflects lateral transfer of the underlying gene, then it is virtually impossible that the same phylogeny will result when another functionally unrelated macromolecule is used as the phylogenetic probe[2].

Many of the Rhodospirillaceae whose cytochromes *c* have been sequenced by Ambler *et al.*[1] have also been characterised in terms of their 16S ribosomal RNAs using the oligonucleotide cataloguing method[3]. Both data sets are analysed by comparable methods: the 16S rRNA catalogues are compared by the binary association coefficient S_{AB} as described previously[9]; and the cytochrome *c* data are represented as per cent sequence homology for each pair of sequences (using the alignments of Dickerson[10], see Table 2 of the accompanying paper[10]). Cluster analysis (average linkage between the merged groups) on these two data sets generates the dendrograms shown in Fig. 1.

The two patterns are in excellent agreement. It is therefore highly unlikely that either one reflects the lateral transfer of genes. Moreover, a number of phenotypic properties of these organisms are consistent with the groups so defined (for details see refs 3, 6 and 10).

The 16S rRNA data indicate that the purple photosynthetic bacteria fall into three major classes—that defined by the bulk of the *Rhodopseudomonas* species and their relatives (class I), that defined by *Rhodopseudomonas gelatinosa* and *Rhodospirillum tenue* (class II) and that defined by *Chromatium* (class III). The first two classes, which comprise the purple non-sulphur bacteria, give no evidence of being specifically related to one another to the exclusion of the last class, the purple sulphur bacteria. Thus if, as has been suggested[10], the former phenotype evolved from the latter, it may have done so several times.

Although a comprehensive survey of 16S rRNA catalogues for the Gram-negative bacteria is not yet available, it is already apparent that the genealogical cluster defined by the purple photosynthetic bacteria is far more extensive phylogenetically than had been generally realised; each of the above-defined three classes of purple photosynthetic bacteria also contains representatives of various major nonphotosynthetic Gram-negative groups, for example, pseudomonads, enterics and vibrios[8]. Thus it would seem that many of the Gram-negative bacteria have arisen as nonphotosynthetic offshoots of photosynthetic ancestors, and the theory that the photosynthetic groups of bacteria are largely phylogenetically distinct from nonphotosynthetic groups is incorrect.

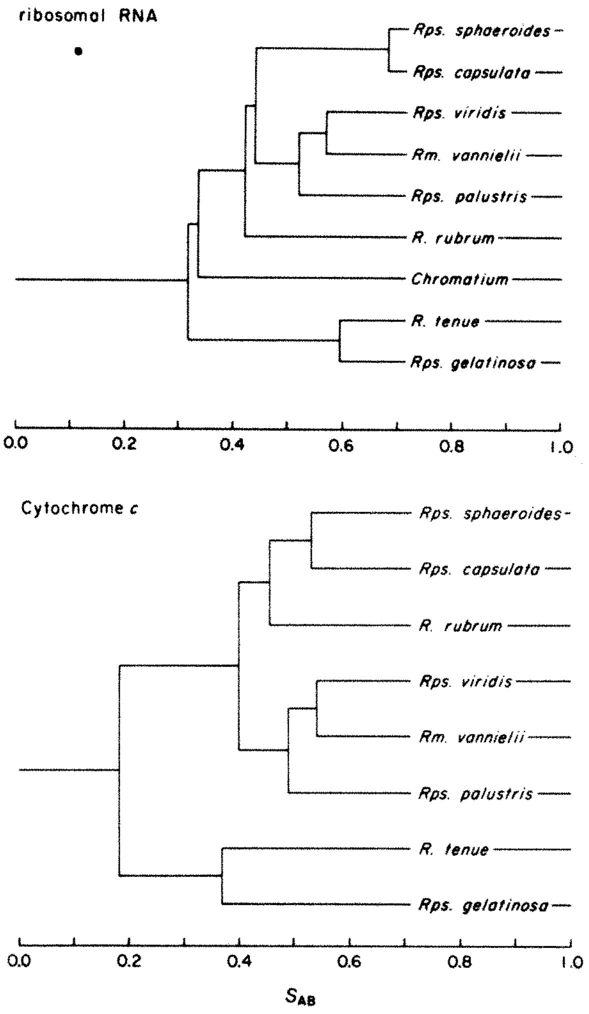

Fig. 1 The relationship among various purple photosynthetic bacteria as determined by 16S ribosomal RNA sequence comparisons, and cytochrome *c* sequence comparisons. *Rps.*, *Rhodopseudomonas*, *R.*, *Rhodospirillum*; *Rm.*, *Rhodomicrobium*.

An alternative explanation for the third argument of Ambler *et al.*—the non-congruence of phylogenetic trees derived from different proteins—is that their finding reflects the limitations in the use of small macromolecules such as cytochrome *c* for genealogical measurement. For a macromolecule to be useful as an evolutionary clock it must maintain functional and tertiary structural constancy over the group of organisms being considered[11,12]. Changing these collective properties seemingly involves clusters of selected, and therefore relatively rapid, changes in genetic sequence, making the molecule an inexact measure of phylogenetic distance at best. Bacterial genealogies encompass considerably greater phylogenetic distances and varieties of niches than genealogies within the higher organisms. Consequently it is not surprising that the conditions of constancy of tertiary structure and function are often not found in the bacteria. The three types of protein studies by Ambler *et al.*—cytochromes c_2 and c_{551}, cytochrome c' and the high potential iron sulphur protein[4]—seem to confirm this point. It is, therefore, not surprising that these three types of macromolecules yield non-congruent phylogenetic trees. For reasons not discussed here we feel that a large macromolecule such as the 16S rRNA is less susceptible to the difficulties which tend to arise when using the smaller macromolecules as genealogical probes.

Isolation of the structural gene for alcohol dehydrogenase by genetic complementation in yeast

Valerie M. Williamson, Jeffrey Bennetzen & Elton T. Young

Department of Biochemistry

Kim Nasmyth & Benjamin D. Hall

Department of Genetics, University of Washington, Seattle, Washington 98195

Alcohol dehydrogenase (ADH) catalyses the interconversion of acetaldehyde and ethanol. This reaction is the final step during alcoholic fermentation in yeast and the initial step in the metabolism of ethanol in a wide variety of organisms. The regulation of ADH is now being studied in several organisms, notably yeast[1–4], *Drosophila*[5], maize[6] and man[7,8]. These organisms contain multiple ADH isozymes which are differentially expressed. The budding yeast *Saccharomyces cerevisiae* is particularly suitable for study because of the potential for genetic analysis of enzyme regulation and structure. Yeast possesses three distinct ADH isozymes[2]. In the presence of glucose ADHI (the 'classical' yeast ADH) is expressed whereas ADHII is repressed. A third enzyme, mADH, is associated with mitochondria. Mutants lacking each of these enzymes have been isolated by virtue of their greater tolerance to allyl alcohol[1], which is converted by ADH to the toxin, acrolein. There is no evidence as to whether the regulation of any one of these enzymes is under transcriptional control. Availability of recombinant DNA clones containing the respective genes would be of obvious value in resolving this problem. We describe here the use of the newly developed technique of yeast transformation[9–11] to isolate recombinant plasmids that contain the structural gene for ADHI (*ADC*1). These plasmids were selected from a pool of plasmids containing yeast DNA by virtue of their ability to complement the growth defect of yeast strains completely lacking ADH activity. Using DNA sequencing, they have been shown to contain the structural gene for ADHI.

The vector used for constructing the yeast DNA pool was the plasmid YRp7 (ref. 11). YRp7 is composed of a 1.4-kilobase *Eco*RI fragment containing the yeast *TRP*1 gene inserted into the *Eco*RI site of pBR322 (ref. 12). The fragment containing *TRP*1 confers on the hybrid plasmid the ability to replicate autonomously in yeast as a low copy number closed circular molecule[11]. Because it need not integrate into the chromosome, YRp7 will transform *trp*1 strains with high efficiency (10^4–10^5 transformants per μg DNA).

The construction of a pool of yeast sequences in YRp7 will be described in more detail elsewhere (K. N. and S. I. Reed, in preparation). Briefly, yeast DNA was partially cleaved with restriction endonuclease *Sau*3A, a 4-base pair recognition site enzyme which produces cohesive ends homologous to those produced by BamHI. The DNA fragments were separated by centrifugation in sucrose gradients and fragments larger than 5 kilobases were ligated into the *Bam*HI site in the tetracycline-resistance gene of YRp7. The pool of recombinant plasmids so created (>25,000 independent tet^s clones) was stored and amplified by transformation of *Escherichia coli* to ampicillin resistance.

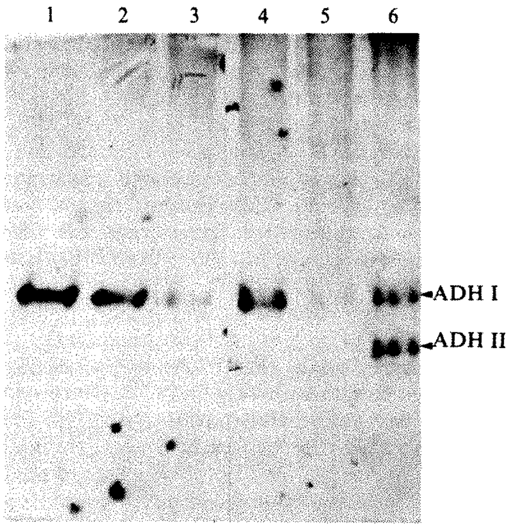

Fig. 1 Screening of transformed yeast for ADH activity. A *trp*1 strain lacking all ADH isozymes (302-21; *mat*α, *trp*1, *his*4, *adc*1, *adm*, *adr*2) was selected from a cross of strain SF-1C-M3 (donated by M. Ciriacy) and strain H293-4-2 (provided by L. Hartwell). The procedure for yeast transformation was essentially that described by Beggs[10]. Cells were plated in a 3% agar overlay lacking tryptophan and containing 2% glucose. The nine large Trp^+ colonies obtained after transformation with the YRp7 yeast pool were plated on medium lacking tryptophan. Extracts from cells grown to stationary phase in medium lacking tryptophan were analysed for ADH activity by spectrophotometric analysis of NAD^+ reduction when ethanol was added as substrate[1]. Aliquots of cell extracts containing approximately 22 μg of protein were electrophoresed into a 5% polyacrylamide slab gel. The electrophoresis system used was adapted from the Tris–glycine system of Davis[18]. The sample was applied to the gel in buffer containing 50 mM Tris–HCl, *p*H 6.8, 25% glycerol and 100 mM β-mercaptoethanol, with bromphenol blue as an indicator. The stacking gel consisted of 3% acrylamide, 0.08% bisacrylamide, 0.12% TEMED, 0.2% ammonium persulphate and 125 mM Tris–HCl, *p*H 6.8. The running gel consisted of 5% acrylamide, 0.13% bisacrylamide, 0.03% TEMED, 0.3% ammonium persulphate and 375 mM Tris–HCl, *p*H 8.8. Electrophoresis buffer was 25 mM Tris and 192 mM glycine and electrophoresis was carried out at 150 V for 3 h at 4 °C. The gel was then stained for ADH activity[19]. In the example shown, wells 1–5 contain extracts from the transformants 9T1–9T5, respectively. Well 6 contains extract from the strain which was used as the yeast DNA source in constructing the DNA vector pool.

The selective technique used for identifying plasmids containing an ADH gene was based on the inability of yeast mutants lacking ADHI to grow in the absence of respiration[13]. Such mutants will not grow at all in the presence of antimycin A (M. Ciriacy, personal communication) and grow only poorly when embedded in a 3% agar overlay. A *trp*1 strain lacking all ADH isozymes was transformed with plasmid DNA prepared from the pool using the technique described by Beggs[10] (see Fig. 1 legend). Nine large colonies (9T1–9T6; 10T1–10T3), a frequency of one per 4×10^3 Trp^+ transformants, were produced after incubation at 30 °C for 1 week. Seven out of the nine contained ADH activity after growth to stationary phase (Fig. 1). When analysed by electrophoresis on a native polyacrylamide gel, all seven displayed a band of activity co-migrating with ADHI from the donor strain (Fig. 1).

The Adc^+ transformants fell into two classes. Two, 9T2 and 10T2, had ADHI levels comparable to wild type. They were allyl alcohol sensitive, antimycin A resistant and stable for the Trp^+ phenotype. These stable transformants were further analysed by mating with an ADH-null *trp*1 strain. Tetrad analysis of the haploid progeny showed that both the Trp^+ and

0028-0836/80/020214—03$01.00

Adc$^+$ phenotypes segregated 2:2 (Trp$^+$Adc$^+$:Trp$^-$Adc$^-$), that is, only parental combinations were observed. This result indicates that these normally unlinked genes are now linked and have integrated into a chromosomal site. The site of integration was not determined. The second class of transformants contained 10–100% of the wild-type ADHI activity. When plated on YEPD plates, cells from these transformants produced a mixture of large and small colonies and rapidly lost the ability to grow without tryptophan. These colonies presumably contained autonomously replicating plasmids which were readily lost in the absence of selection, a property characteristic of YRp7 (ref. 11).

Plasmid DNA was isolated from transformant 9T6 and amplified in *E. coli* as described in Fig. 2 legend. Restriction enzyme digestion of the plasmid DNA (pY9T6) isolated from three different *E. coli* clones transformed with plasmid DNA from transformant 9T6 showed that all were identical. Three different plasmids, one of which (pY9T5) shared common yeast restriction fragments with pY9T6, were similarly isolated from yeast transformant 9T5.

Plasmids pY9T5 and pY9T6 were used to retransform strain 302–21 (ADH-null). With pY9T6, 0.06% of the cells surviving treatment were transformed to Trp$^+$, and with pY9T5, 0.02% were similarly transformed. All Trp+ cells were able to grow in the presence of antimycin A. Eight transformants were grown in medium lacking tryptophan and the extracts were assayed for ADH activity. All had near wild-type levels of ADH activity and produced an active enzyme which co-migrated with ADHI during electrophoresis. Both the Trp$^+$ and Adc$^+$ phenotypes were unstable in the absence of selection and were lost coordinately.

The above results clearly show that both pY9T5 and pY9T6 are capable of complementing the ADHI deficiency of 302–21 caused by the *adc*1 mutation. However, apart from the fact that ADHI-defective mutants have been found only at this locus[2], there is little compelling evidence that the *ADC*1 locus in fact constitutes the structural gene for the enzyme. To resolve this problem, we have tested the ability of pY9T5 and pY9T6 to hyridise to a ^{32}p-labelled cDNA probe prepared from an RNA fraction highly enriched for ADHI mRNA (J.B., unpublished). Both plasmids hybridised strongly (results not shown), suggesting that the locus is indeed the structural gene. Restriction maps of pY9T5 and pY9T6 (Fig. 2) show that the two plasmids contain about 4.1 kilobases of overlapping sequence but that their inserts are of different sizes and are in the opposite orientation in the YRp7 vector. DNA sequence was obtained

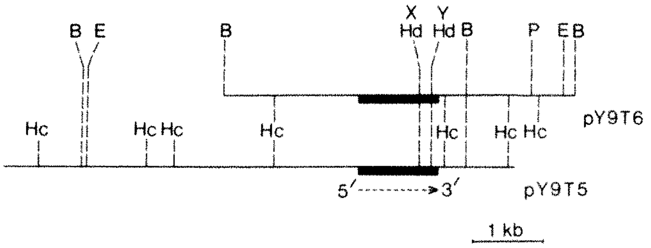

Fig. 2 Restriction endonuclease cleavage sites on the overlapping yeast DNA inserts of recombinant plasmids pY9T5 and pY9T6. Plasmid DNA was prepared as described by Livingston and Klein[20] from the unstable yeast transformants after growth in the absence of tryptophan and in the presence of antimycin A. Transformation of *E. coli* to ampicillin resistance produced approximately 100 colonies per µg DNA, all of which were tetracycline sensitive. Plasmid DNA was purified from *E. coli* by a modification of the procedure of Elwell *et al.*[21]. Single and double restriction digests of the DNA were analysed on horizontal 0.7% agarose gels. The position of the *ADC*1 locus was first determined by hybridisation to Southern filter[22] replicas of these agarose gels with radioactive cDNA complementary to an ADHI mRNA-enriched RNA fraction. A detailed description of the preparation and use of this cDNA will be presented elsewhere. The position and extent of the *ADC*1 structural locus was further defined by the DNA sequencing results (Fig. 3). The cleavage sites of relevant restriction nucleases are designated as follows: B(*BamHI*), E(*Eco*RI), Hc(*Hinc*II), Hd (*Hin*dIII), P(*Pst*I); X and Y designate specific *Hin*dIII sites which are referred to in the text and Fig. 3. The extent and position of the structural *ADC*1 locus is shown by the solid bars and the direction of transcription by the arrow below the bars. Restriction maps of the entire plasmids (not shown) demonstrated that the *ADC*1 locus is in the opposite orientation in pY9T5 and pY9T6 relative to the YRp7 vector sequences. The *Bam*HI site at the left end of pY9T6 is a cloning artefact produced by ligation of the *Sau*3A sticky end into the pBR322 *Bam*HI site. The pY9T5 insert is 7.2 kilobases and the pY9T6 insert 4.9 kilobases. Overlap between pY9T5 and pY9T6 defines a 4.1-kilobase sequence which is sufficient for ADHI expression.

Fig. 3 Partial DNA sequence of the *ADC*1 locus. The DNA sequence coding for amino acid residues 213–332 in the ADHI protein was determined by the technique of Maxam and Gilbert[23]. 100 µg of pY9T6 DNA was limit digested with *Hin*dIII then dephosphorylated with bacterial alkaline phosphatase and labelled with ^{32}P at the 5′ end using T4 polynucleotide kinase as described by Richardson[24]. DNA was then precipitated with ethanol to remove unreacted [γ-^{32}P]ATP. Half the labelled DNA was base denatured and loaded onto a long (38 cm) 6% native acrylamide gel. Electrophoresis for 18 h at 150 V resolved the separated strands of the 150-base pair restriction fragment between *Hin*dIII sites X and Y (Fig. 2). DNA fragments containing the other two pertinent labelled ends were isolated on 0.7% agarose gels, electroeluted, purified over DE-52, cleaved with a second restriction enzyme and resolved on another 0.7% agarose gel. Modifications and cleavages of the four electroeluted DNA samples were done by standard Maxam and Gilbert procedures[23]. Products were analysed on 8% and 20% acrylamide, 7 M urea sequencing gels which were either 0.5 mm or 0.7 mm thick. All but one of the 120 amino acids derived from the DNA sequence agree with the published amino acid sequence of the ADHI protein[14,15] for amino acid residues 213–332. Our sequence demonstrates that residue 236 is asparatic acid rather than asparagine. The restriction endonuclease sites shown were detected by scanning the derived DNA sequence. Only the *Hae*III and *Hin*dIII sites have been confirmed by actual restriction endonuclease digestion.

for the region surrounding *Hin*dIII sites X and Y (Fig. 3). Comparison of this sequence with the known amino acid sequence for ADHI[14] shows conclusively that these plasmids contain the structural gene. Figure 3 shows that the DNA sequence corresponds to an uninterrupted sequence encoding amino acids 213–332 in the ADHI protein with only one amino acid difference from the published sequence[14,15]. The extent of the coding sequence, if there are no intervening sequences, is indicated in Fig. 3. The ability of these plasmids to complement the growth defects of an ADH-null strain, together with the presence of normal levels of ADH activity, demonstrates that a functioning ADHI gene is present on both pY9T5 and pY9T6.

One reason for investigating ADH in yeast is to compare two genes which code for closely related proteins, ADHI and ADHII[15], but which are expressed in different conditions. As mentioned earlier, all the transformants which were selected for ADH activity contained ADHI, the constitutive enzyme. The absence of transformants containing ADHII was to be expected because the repression of this enzyme by the glucose present in our conditions of transformation would prevent it from complementing the growth defect of the recipient strain. The use of DNA from an available constitutive mutant of ADHII[4] should alleviate this problem and allow the ADHII structural gene (*ADR*2) to be cloned in a similar manner to *ADC*1. Alternatively, as ADHI and ADHII differ in only 15 of 284 amino acid positions[15], it is likely that their DNA sequences will cross-hybridise sufficiently to allow the already cloned ADC1 sequence to be used as a hybridisation probe for *ADR*2.

The use of complementation to isolate genes from a plasmid or phage pool is not new. Several yeast genes, for instance, *LEU*2, *HIS*3, *URA*3, and *TRP*1, have been isolated[11,16,17] by virtue of their ability to complement equivalent mutations in *E. coli*. By using yeast rather than *E. coli* cells as the recipient in transformation experiments, this same approach can be used to clone genes for which there is no analogous *E. coli* function. Preliminary experiments in our laboratory have shown that this potential is realisable for several different types of gene, for instance, those necessary for the cell division cycle (K. N. Nasmyth and S. I. Reed, in preparation) and mating. One might also speculate, based on the precedent set by the expression of yeast genes in *E. coli*, that yeast transformation may be a valuable technique for identifying and isolating genes from other eukaryotes. In particular, the system described here may prove useful for the isolation of ADH genes from other organisms.

We thank Michael Ciriacy for providing ADH-deficient mutants and information on their properties, and Christopher Wills and Hans Jornvall for providing information on ADHII protein sequence before publication. This work was supported by the USPHS.

Trans-complementable copy-number mutants of plasmid ColE1

Andrea J. Twigg & David Sherratt

School of Biological Sciences, University of Sussex, Falmer, Brighton, UK

Plasmid ColE1, like many other small non-conjugative plasmids, is present in multiple copies (about 15 per chromsome equivalent) in *Escherichia coli* cells[1,2]. Because of their high copy number, the replication of such plasmids has been described as 'relaxed', even though there is good evidence that it is strictly controlled: ColE1 derivatives have characteristic but different copy numbers[2] and ColE1 copy-number mutants have been characterised[3–5]. No plasmid-specified protein is essential for the replication of ColE1 and related plasmids, as extensive replication can occur in chloramphenicol-treated cells[6], in plasmid-free chloramphenicol-treated cells transfected with a hybrid ColE1/phage replicon and *in vitro* in extracts derived from plasmid-free cells[8]. Nevertheless, it is possible that a plasmid-specified protein is involved in ColE1 replication control in viable cells. Here we show that deletion of a given non-essential region from ColE1-like plasmids results in a raised copy number. Such plasmids are stably maintained and have their copy number returned to normal when a complementing plasmid is present in the same cell, indicating that a plasmid-specified diffusible gene product regulates the plasmid content of ColE1-containing cells. Deletion of the equivalent region from the cloning vector pBR322 gives a derivative which has a raised copy number and which has also lost its origin for conjugal transfer; unlike pBR322, it cannot be mobilised.

Several chloramphenicol-resistant ($\mathrm{Cm^r}$) deletion derivatives of ColE1 were constructed by mixing partially *Hae*II-digested ColE1 DNA with a purified *Hae*II fragment, specifying $\mathrm{Cm^r}$, of pACYC184 (ref. 9). After ligation *in vitro*, the DNA was transformed into *E. coli* K12 [DS410 (ref. 10)], selecting for $\mathrm{Cm^r}$. The structure of some of the resulting plasmids is given in Fig. 1(*a*) and the plasmid DNA content of cells containing these mutants is shown in Table 1. For all mutants tested (including others not shown here), there is a direct correlation between raised plasmid level and the absence of the ColE1*Hae*II-C fragment. Mutants containing *Hae*II-C have a plasmid level close to that of ColE1, whereas those deleted for *Hae*II-C have a five to sevenfold increase in plasmid content. To determine whether *Hae*II-C contains all or part of a gene specifying a repressor for copy-number control and/or a site at which it acts, we attempted the complementation of raised copy number using the related plasmid, ColK. Although this plasmid is compatible with ColE1[11], the two plasmids show partial homology (D.S., unpublished) and have interchangeable mobility functions[11]. The effect of ColK and some of its deletion derivatives (Fig. 1*b*) on the ColE1 copy mutants is shown in Table 1. Whereas the presence of ColK reduced the plasmid level of all ColE1 copy mutants, the unrelated plasmid pSC101 and some of the ColK derivatives had little effect on ColE1 plasmid content. This suggests that we are observing true complementation rather than a nonspecific lowering of individual plasmid content. Examination of the structure of the ColK plasmids that have no effect on the ColE1 copy mutants indicates that the complementing gene product (repressor) is specified by a gene whose expression to give an active gene product disappears when ColK*Hae*II-B is deleted; the gene could be wholly contained on the fragment or extend into the E or even C fragment of ColK. This region corresponds in position and is probably partially homologous to the *Hae*II-C fragment of ColE1, thus supporting the idea that this region in both ColE1 and ColK encodes a repressor of plasmid replication. The site of action of this repressor must be present in all the copy mutants.

0028–0836/80/020216—03$01.00

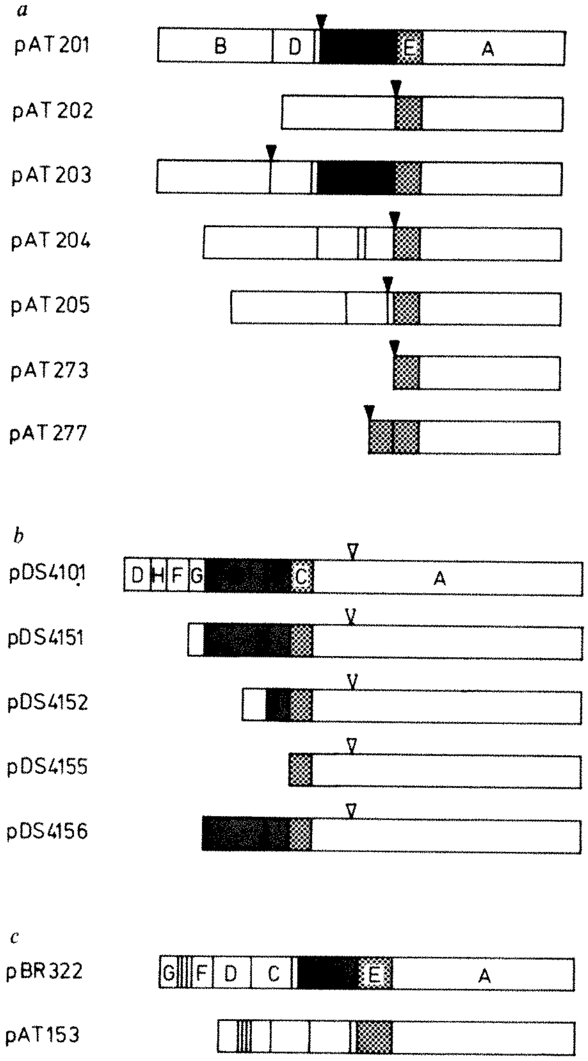

Fig. 1 Structures of the plasmids used. *a*, Cm^{r} ColE1 derivatives. pAT201, and pAT203 have the entire ColE1 genome with the Cm^{r} *Hae*II fragment of pACYC184[9] (▼) inserted at either of two *Hae*II sites; the other plasmids have various ColE1 *Hae*II fragments deleted. *b*, Ap^{r} ColK derivatives. pDS4101 is ColK: : Tn1. The other plasmids are deletion derivatives of this. ▽ Indicates intact Tn1, and V indicates that some of the Tn1 internal *Hae*II fragments have been deleted. *c*, pBR322 and its *Hae*II deletion derivative pAT153. Vertical lines indicate *Hae*II sites. Light stippling indicates the *Hae*II fragment carrying the origin of replication and heavy stippling indicates the region encoding the gene product (repressor) that maintains normal plasmid copy number.

Table 2 Conjugal mobility of plasmid cloning vectors

Plasmid vector	Mobilisation promoted by conjugative plasmid R64*drd*11*	Mobilisation from a R64 *drd*11 ColK† cell
pBR322	$<8\times10^{-6}$	9×10^{-2}
pAT153	$<1\times10^{-5}$	$<4\times10^{-6}$
pACYC184	$<9\times10^{-6}$	$<2\times10^{-5}$

* Frequency of R64-receiving recipients that inherit given factor.

† ColK is a natural relative of ColE1 that specifies *trans*-acting mobility proteins that are interchangeable with those of ColE1 for R64*drd*11-promoted transfer[11].

To test if deletion of the equivalent region from plasmids derived from natural relatives of ColE1, results in increased copy number, we partially digested with *Hae*II the cloning vector pBR322 (refs 12, 13), which is ampicillin resistant (Ap^{r}) and tetracycline resistant (Tc^{r}) and is derived from pMB1, closely related to ColE1[14]. Inspection of the published sequence of the pBR322 *Hae*II-B fragment[13] with that available to us for the ColE1*Hae*II-C fragment, shows that most of pBR322 *Hae*II-B is contained within ColE1*Hae*II-C in a highly conserved form (also see ref. 13, page 85). After *in vitro* ligation and transformation, selecting for Ap^{r}Tc^{r}, we isolated a deletion derivative lacking the 0.62-kilobase *Hae*II-B fragment of pBR322 (Fig. 1*c*). Cells containing this plasmid (pAT153) have a 1.5–3-fold greater plasmid content than those containing the parental plasmid. Although this increase is smaller than that for the ColE1 deletion derivatives, we believe that it makes pAT153 a potentially useful cloning vector because of greater plasmid and plasmid gene product yields per ml of culture. pAT153, like pBR322, replicates in chloramphenicol-treated cells. In terms of biological containment for *in vitro* genetic manipulation, pAT153 also has a great advantage over pBR322 in that it has lost *nic*, the transfer origin for conjugal transfer. Whereas pBR322 is efficiently mobilised from cells containing the appropriate conjugative plasmid and ColE1-like mobility proteins, no transfer of pAT153 has been observed (Table 1). It can also be seen that pACYC184 behaves as a *nic*$^{-}$ plasmid. Similarly, ColE1 deletions lacking *Hae*II-C are non-mobilisable because they lack *nic*[15]. The increased gene-dosage effects resulting from the increased copy number of the ColE1 deletion derivatives have also been detected by the increased antibiotic resistance conferred on plasmid-containing cells and by the increased frequency of spontaneous colicin production by cells containing colicin-producing copy mutants (A.J.T., unpublished).

Table 1 Plasmid content of cells containing Cm^{r} ColE1 deletion mutants

		ColE1 plasmid content (as % of chromosomal DNA) when:							
ColE1 derivative	Size (kilobases)	No other plasmid present	ColK present	pSC101 present	pDS4101 present	pDS4155 present	pDS4151 present	pDS4152 present	pDS4156 present
ColE1	6.3	3.8 (0.92)	–	–	–	–	–	–	–
pAT201	7.8	2.8 (0.44)	–	–	–	–	–	–	–
pAT202	5.4	13.9 (2.1)	2.1 (0.31)	–	–	–	–	–	–
pAT203	7.8	4.5 (0.96)	–	–	–	–	–	–	–
pAT204	6.9	16.5 (1.2)	2.9 (0.53)	13.0 (0.98)	0.7 (0.10)	12.0 (1.4)	2.5 (0.38)	20.9 (3.1)	0.8 (0.20)
pAT205	6.2	17.7 (2.7)	1.4 (0.60)	–	1.4 (0.53)	13.7 (0.96)	0.8 (0.23)	15.0 (1.8)	0.5 (0.15)
pAT273	3.9	20.5 (1.8)	1.9 (0.32)	13.6 (1.6)	–	–	–	–	–
pAT277	4.3	20.6 (2.0)	1.4 (0.28)	19.9 (2.2)	0.5 (0.21)	12.2 (1.6)	2.1 (0.29)	18.8 (1.1)	0.5 (0.24)

Plasmid content values are means of at least three determinations carried out as described in Fig. 2 legend. These values can be easily converted to copy number per genome equivalent (3.8×10^{3} kilobase pairs). Values in parentheses are standard deviations. –, Not determined.

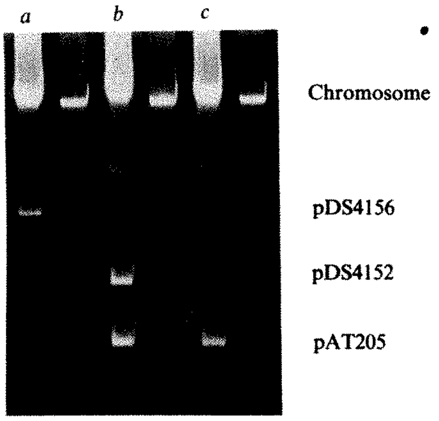

Fig. 2 Copy-number determination. Representative 1% agarose gel electrophoresis of total cell lysates. Stationary phase cells (about one colony equivalent) from either selective agar or a liquid culture were resuspended in 250 μl of 40 mM Tris acetate, 20 mM sodium acetate, 1 mM disodium EDTA (*p*H 8.2) electrophoresis buffer containing 1% SDS, 2% Ficoll and 0.01% bromophenol blue. After heating at 65° C for 30 min and vortex mixing, 50 μl each of undiluted and 10-fold diluted sample were applied to alternate gel wells. After running (50 V for 4 h) and staining with ethidium bromide (0.5 μg ml^{-1}, 60 min), the UV-fluorescence of the gel was photographed using a range of exposures. Microdensitometer tracings of suitable photographic negatives allowed the relative proportions of plasmid and chromosomal DNA to be determined for each lysate. This gel shows the results of copy-number complementation by ColK derivatives. *a*, pDS4156+pAT205; *b*, pDS4152+pAT205; *c*, pAT205 alone. The fainter alternate tracks are the respective 10-fold diluted samples. Although most of our copy-number determinations were made on stationary phase cells, the same relative differences between ColE1 and its copy mutants were observed in exponentially growing cells.

The presumptive replication repressor described above seems not to be intimately involved in determining plasmid incompatibility[16,17], the phenomenon that prevents two closely related replicons stably coexisting within a cell. ColE1 and ColK have cross-reacting repressors, but are completely compatible, whereas two ColE1 derivatives lacking *Hae*II-C are not stably co-maintained. Moreover, other ColE1 sequences are involved in determining plasmid copy number. For example, an insertion of some 30 base pairs in part of the ColE1 region essential for autonomous replication results in a copy-number phenotype[4,5]. The RNA transcript of the region seems to be important in specifying copy number[5]. It will be of interest to study the interactions of the two types of copy-number mutant.

Excision sequences in the mitochondrial genome of yeast

Claire Gaillard, François Strauss & Giorgio Bernardi

Laboratoire de Génétique Moléculaire,
Institut de Recherche en Biologie Moléculaire, Paris, France

It is well established that spontaneous cytoplasmic 'petite' mutants of *Saccharomyces cerevisiae* have mitochondrial genome units in which an excised segment of the parental wild-type genome has been tandemly amplified (Fig. 1), so that the excised segment becomes the repeat unit of the petite genome; the latter may in turn undergo further deletions leading to secondary petite genomes having shorter repeat units (see ref. 1 for a brief review). Recent investigations[2] on the mitochondrial genomes of several spontaneous petite mutants have shown that frequently the ends of the excised segment correspond to short sequences of the wild-type genome which are extremely rich in GC, the GC clusters; alternatively, they seem to be located in the long AT-rich stretches, the AT spacers, which form at least half of the genome. As sequence repetitions have been demonstrated in both GC clusters and AT spacers[2–5], it is very likely that excision takes place by a mechanism involving illegitimate site-specific recombination events between homologous sequences, as previously postulated[1]. We show here that the sequences involved in the excision of a particular spontaneous petite genome are direct nucleotide repeats located in the AT spacers.

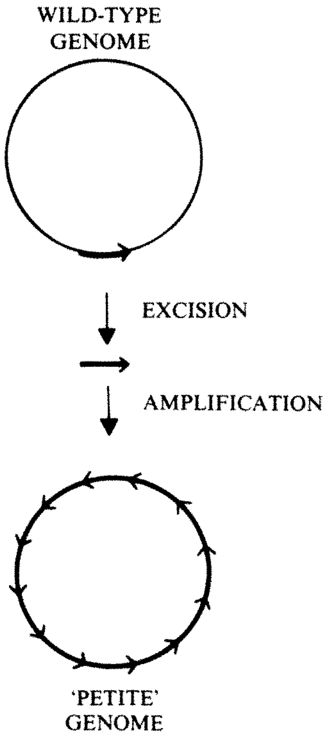

Fig. 1 Scheme of the process leading to the formation of spontaneous petite genomes. A segment of a mitochondrial genome unit from wild-type yeast cells is excised and tandemly amplified to yield the mitochondrial genome unit of a petite mutant. The excised segment from the wild-type genome becomes the repeat unit of the petite genome. This may in turn undergo further deletions leading to secondary petite genomes having simpler repeat units.

0028-0836/80/020218—03$01.00

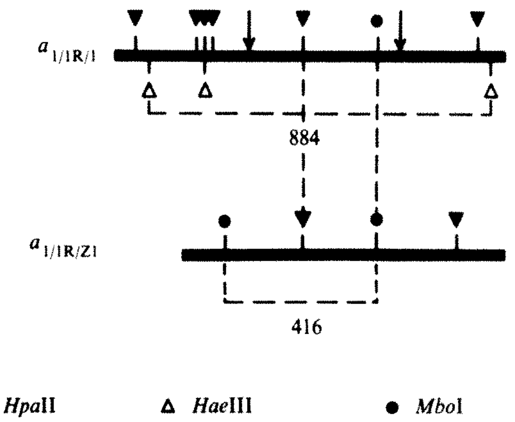

Fig. 2 Restriction enzyme maps of the repeating units of the mitochondrial genomes of two spontaneous petite mutants. The molecular weights of the repeat units are indicated (horizontal broken lines), along with the positions of *Hae*III (Δ), *Hpa*II (▼) and *Mbo*I(●) restriction sites. The vertical broken lines indicate corresponding restriction sites in the repeat units of the two genomes. Arrows indicate the approximate positions of excision sites as obtained from the data of Fig. 3.

Our approach was to sequence the repeat unit of the mitochondrial genome of a spontaneous petite mutant, $a_{1/1R/1}$, which was supposed to contain the repeat unit and the flanking sequences of another spontaneous petite mutant, $a_{1/1R/Z1}$. Both petite genomes had been previously characterised[2]; they originated from the same region of the parental wild-type mitochondrial genome (between map positions 27 and 46, ref. 6) and their restriction maps were known (Fig. 2); the DNA from $a_{1/1R/Z1}$ hybridised on restriction fragments from wild-type DNA corresponding to the larger *Hae*III fragments and to the two largest *Hpa*II fragments of $a_{1/1R/1}$, and shared a *Hpa*II–*Mbo*I fragment with $a_{1/1R/1}$; finally, the sequence of the repeat unit of $a_{1/1R/Z1}$ was known[5].

The nucleotide sequence was determined, using the method of Maxam and Gilbert[7], on both mitochondrial DNA prepared from $a_{1/1R/1}$ and its *Mbo*I repeat unit inserted in the *Bam*HI site of pBR322 plasmid and amplified in a *rec*$^+$ *Escherichia coli* strain (HVC46; C600 *leu*$^-$, *thi*$^-$, *lac*$^-$, *tonA*, *supE*44, *hsdR*, *hsdM*). The same sequence was found in both cases (Fig. 3). The repeat unit of $a_{1/1R/1}$ is 884 nucleotides long and contains, between positions 278 and 693, a 416-nucleotide segment which is identical to the sequence of the repeat unit of $a_{1/1R/Z1}$ (ref. 5), except for two base pair changes, which are indicated by an asterisk in Fig. 3. The most important feature of the sequence of $a_{1/1R/1}$ is that the initial nonanucleotide of the repeat unit of $a_{1/1R/Z1}$, AATAATATA, is repeated just after the end of the repeat unit; if allowance is made for one A·T to T·A change, these direct repeats are, in fact, 13 nucleotides long. This situation is reminiscent of those found on both sides of insertion sequence IS*1* and of transposon Tn*9* in *E. coli*, where two direct repeats of 9 base pairs were found[8,9]. It provides evidence consistent with the excision model proposed previously, and raises the interesting possibility that segments like $a_{1/1R/Z1}$ can be transposed onto other mitochondrial genome units and contribute to the changes in length observed in genome units belonging to different strains[10]. Incidentally, the data do not allow one to decide whether the repeat unit of $a_{1/1R/Z1}$ was excised from the parental wild-type genome or from $a_{1/1R/1}$, although the latter explanation seems the more likely. This is not an essential point, however, as it is known that the same excision process is operative in wild-type and petite genomes[2].

Several other features of the sequence of $a_{1/1R/1}$ are worth mentioning: (1) two direct AT repeats, 16 nucleotides long, containing the nonanucleotides flanking the $a_{1/1R/Z1}$ sequence,

Fig. 3 Nucleotide sequence of the repeat unit of the mitochondrial genome of spontaneous petite mutant $a_{1/1R/1}$. Cutting sites of *Hae*III (Δ), *Hpa*II (▲), *Mbo*I (●) and *Mbo*II (○) are indicated. The sequence between positions 278 and 693 is identical to that of $a_{1/1R/Z1}$ (ref. 15) except for asterisked base pairs 306 and 401, which are replaced by G·C and C·G, respectively, in $a_{1/1R/Z1}$. Boxed sequences correspond to the nonanucleotides flanking the sequence of $a_{1/1R/Z1}$. Lines indicate repeated sequences (see text).

are found at positions 40–55 and 749–764 (these are labelled b in Fig. 3); (2) two GC-rich repeats, 25 nucleotides long with only one A·T to T·A change, are found at positions 132–156 and 853–877 (these are labelled c in Fig. 3); the first one is part of a 65-nucleotide stretch very rich in GC (GC = 65%), which accounts for the higher GC level of $a_{1/1R/1}$ (GC = 16.2%) compared with $a_{1/1R/Z1}$ (GC = 14.2%); (3) a 20-nucleotide sequence formed by five repeats of the sequence TTAA is found at positions 809–828; (4) symmetrical sequences are found in the GC cluster at position 150, in agreement with previous predictions[10] and findings[3,4]; (5) other sequence features of $a_{1/1R/1}$ are common with $a_{1/1R/Z1}$ and have already been mentioned[5]; the most remarkable one is a 47-nucleotide stretch (369–415) formed by a palindrome 23 nucleotides long (378–400) and a small symmetrical sequence TTATT (402–406), which are flanked by two symmetrical GC clusters (369–377 and 407–415).

The main conclusion of the present work is that crossing-over involving short homologous sequences is indeed the most likely mechanism underlying the excision of spontaneous petite genomes. Sequences used in the excision of other spontaneous petite genomes are being investigated in our laboratory. Some of the genomes under consideration are also encompassed by $a_{1/1R/1}$, and it will be interesting to see which other sequences of $a_{1/1R/1}$ are involved in excision. We expect to find among them some or the other repeats of $a_{1/1R/1}$.

Another point of interest is that the presence of direct repeats in its sequence has not caused any instability of the $a_{1/1R/1}$ repeat unit as propagated in a *rec*$^+$ *E. coli*; it should be stressed, however, that monomers of the repeat unit were cloned and that oligomers were not tested.

Finally, an inspection of the sequence of $a_{1/1R/1}$ fails to reveal the presence of any gene, a conclusion confirmed by the present knowledge of codons used for the synthesis of mitochondrially encoded proteins[4,11] and of tRNA gene sequences[12]. The only function left in this petite genome (as well as in $a_{1/1R/Z1}$) is replication. As the excision process leading to the formation of spontaneous petite genomes is extremely conservative as far as the excised sequence is concerned[2] (in contrast to that induced by ethidium, where sequence rearrangements are frequent [13]), each repeat unit of $a_{1/1R/1}$ should contain a site used for the initiation of DNA replication. A good candidate is the 80-nucleotide sequence centred around position 412. This sequence, (which contains the remarkable stretch, 369–415, mentioned above), is present not only in the two overlapping genomes $a_{1/1R/1}$ and $a_{1/1R/Z1}$, but also in another one[14], b, whose 875-nucleotide repeat unit is derived[2] from an entirely different region of the parental wild-type genome (map positions 64–76, ref. 6). If a site for the initiation of DNA replication is present in each repeat unit of these petite genomes, a high replication rate may be expected. This indeed seems to be the case, as the three petites under consideration are 'supersuppressive', namely petites whose mitochondrial genomes compete out those of wild-type cells in crosses and become the only ones transmitted to the progeny[14].

Are snRNPs involved in splicing?

Michael R. Lerner, John A. Boyle, Stephen M. Mount, Sandra L. Wolin & Joan A. Steitz

Department of Molecular Biophysics and Biochemistry, Yale University, New Haven, Connecticut 06510

Discrete, stable small RNA molecules are found in the nuclei of cells[1] from a wide variety of eukaryotic organisms[2]. Many of these small nuclear RNA (snRNA) species, which range in size from about 90 to 220 nucleotides, have been well-characterised biochemically[3–6], and some sequenced[7,8]. However, their function has remained obscure. The most abundant snRNA species exist as a closely related set of RNA–protein complexes called small nuclear ribonucleoproteins (snRNPs)[9]. snRNPs are the antigens recognised by antibodies from some patients with lupus erythematosus (LE), an autoimmune rheumatic disease[10,11]. Anti-RNP antibodies from lupus sera selectively precipitate snRNP species containing Ula[7] and Ulb[9] RNAs from mouse Ehrlich ascites cell nuclei, whereas anti-Sm antibodies bind these snRNPs and four others containing U2 (ref. 8), U4, U5 and U6 (ref. 9) RNAs. Both antibody systems precipitate the same seven prominent nuclear proteins (molecular weight 12,000–32,000). All molecules of the snRNAs U1, U2, U4, U5 and U6 appear to exist in the form of antigenic snRNPs[9]. The particles sediment at about 10S and each probably contains a single snRNA molecule. Indirect immunofluorescence studies (refs 12, 13, and unpublished observations) using anti-RNP and anti-Sm sera confirm the nuclear (but non-nucleolar) location of the antigenic snRNPs. Here we present several lines of evidence that suggest a direct involvement of snRNPs in the splicing of hnRNA. Most intriguing is the observation that the nucleotide sequence at the 5′ end of U1 RNA exhibits extensive complementarity to those across splice junctions in hnRNA molecules.

If snRNPs participate in RNA processing, they might be expected to be strictly conserved across those higher eukaryotic species possessing interchangeable transcription and mRNA processing systems (refs 14–17 and P. Chambon, personal communication). Figure 1 shows that the antigenic snRNPs are indeed highly conserved from man to insects. The anti-RNP lanes reveal that mouse snRNPs containing the closely related Ula and Ulb RNAs[9] are replaced by a single U1-containing snRNP in HeLa and fall armyworm cells. Fingerprints (not shown) indicate that the sequence of HeLa U1 RNA is identical to that of mouse U1a[9] and to that of rat U1a[7]; insect U1 RNA has a quite different fingerprint, although it is comparable in size to the mammalian U1. Likewise, when anti-Sm antibody is used, four additional HeLa or insect cell snRNPs that contain RNAs very close in mobility to mouse U2, U4, U5 and U6 are precipitated; again, fingerprints of the HeLa U2, U4, U5 and U6 RNAs are identical to those of mouse(not shown). Also, human antibodies precipitate snRNPs from the nuclei of frog, chicken and sea urchin cells, indicating high conservation of both RNA and protein components of snRNPs in these species as well. No cross-reacting material is detected in tobacco cell, yeast, *Dictyostelium discoideum* or *Escherichia coli* extracts.

A second prediction concerning snRNP involvement in RNA biogenesis is that snRNAs should be present in highest abundance in metabolically active cell types. Figure 2 compares nuclear extracts from liver and from red blood cells (RBC) of chickens. The sucrose gradient profiles (Fig. 2*a*) showing extracts from equal numbers of the two types of nuclei reveal fewer than one-tenth as many 30S hnRNP particles (the highly conserved ribonucleoprotein complexes that bind hnRNA in the nuclei of higher eukaryotes[18–20]) and much less RNA sedimenting in the 10S region in the case of the RBC. Also, gel analysis of

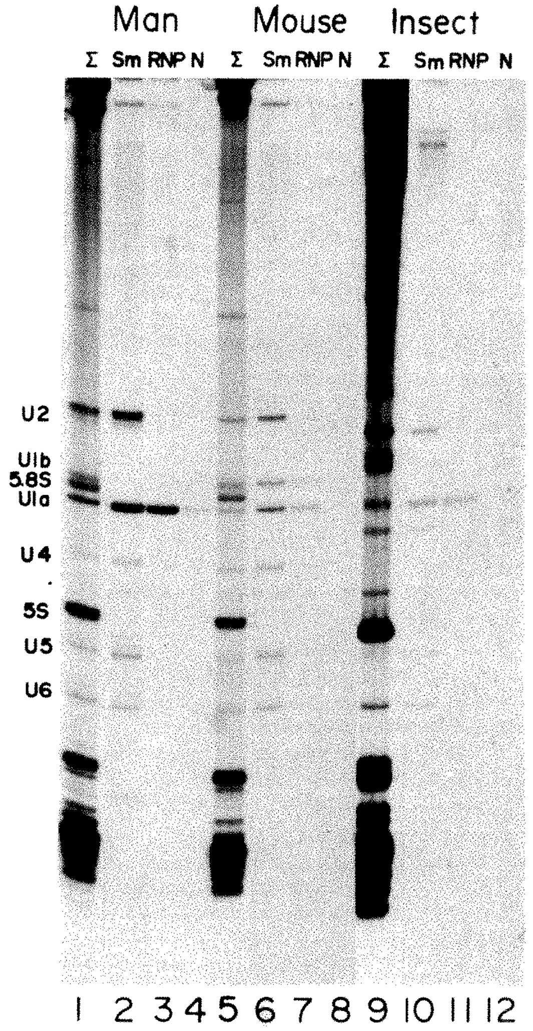

Fig. 1 Comparison of snRNPs from different species. Small RNAs from cell sonicates or immune precipitates from HeLa (lanes 1–4), Ehrlich ascites (lanes 5–8) and fall armyworm (lanes 9–12) cells were prepared as previously described[9] using Pansorbin to obtain the antigen–antibody complexes. The gel contained 10% polyacrylamide, 7 M urea, 1 mM EDTA, 50 mM Tris-borate *p*H 8.3 and was 400×200×0.5 mm. Lanes 1, 5 and 9 show small RNAs in whole cell extracts; 2, 6 and 10 show typical anti-Sm patterns; while 3, 7 and 11 show typical anti-RNP patterns. Lanes 4, 8 and 12 are controls using normal serum.

nuclear RNAs reveals snRNAs in both cases, but about 25-fold fewer in liver than in RBC (Fig. 2*b*, compare lane 2 with lanes 3 and 4). Treatment of the chicken with phenylhydrazine, which raised the level of erythroblasts to about 25% of the total RBC, altered the snRNA gel pattern (not shown) to that characteristic of liver cells (Fig. 2*b*, lane 2). Thus, liver cells, which actively synthesise mRNA, have both higher amounts and a slightly different population of snRNAs than the cryptic nuclei of biosynthetically inactive erythrocytes. Were the result otherwise, it would constitute evidence against snRNP participation in RNA processing.

Finally, a number of workers[4,21-24] have observed snRNAs co-sedimenting with larger nuclear structures, such as the 30S particles that bind hnRNA. We have argued[9] that the snRNAs U1, U2, U4, U5 and U6 are not structural components of 30S hnRNP. Yet, as shown in Fig. 3*a*, *b*, on sucrose gradient fractionation of a nuclear extract prepared from Ehrlich ascites cells, antigenic snRNPs containing these snRNA species do sediment in the 30S region of the gradient. An RNA-labelled U1a*, however, appears only in the 10S region where the free snRNP particles sediment. Fingerprint analysis (Fig. 3*c*) reveals that U1a* is identical to U1a (Fig. 3*d*) except that it lacks the 5′ trimethylated cap moiety plus six additional nucleotides from the 5′ end of the U1a sequence. Further, U1a* is not present in fresh extracts and the RNA–protein complex containing U1a* is fully antibody precipitable, strongly suggesting that U1a* is an *in vitro* degradation product of U1a. Thus, the absence of a short region at its 5′ terminus seems to prevent the U1a-containing snRNP from co-sedimenting with larger structures containing hnRNA.

It is interesting that several of the residues missing in U1a* fall within a region of U1a which is extensively complementary to sequences across splice junctions in hnRNAs (Fig. 4). DNA sequences corresponding to the ends of 43 introns were analysed (Table 1). Redundant sequences (those which are identical and occur in the same position on homologous RNAs) were discarded, leaving 26 unique sequences at the 5′ ends and 31 unique sequences at the 3′ ends of introns. The two consensus splice junction sequences are presented in Fig. 4*a*; in each position, the frequency of occurrence of the most common base is indicated by underlining as described in the legend. Potential base-pairing interactions between these regions and the nucleotide sequence at the 5′ end of U1a[7] or U1b RNA[9] are also shown. Note that the complementarity of U1 to the consensus sequence at the 5′ end of introns involves eight contiguous residues, plus an adjacent nucleotide (three bases before the splice point) which is generally either C or A. (It seems reasonable to consider that the $\overset{A}{C}$ position is also complementary since A·G base pairs are observed where the two strands of an RNA helix diverge in yeast tRNA^{Phe} (ref. 25).) Of the 26 5′ junction sequences, all but one has the dinucleotide GU immediately adjacent to the splice point and at least five (usually six) bases of the consensus sequence. Similarly, at the 3′ end of introns, all but one of the 31 unique sequences has the dinucleotide AG, and all

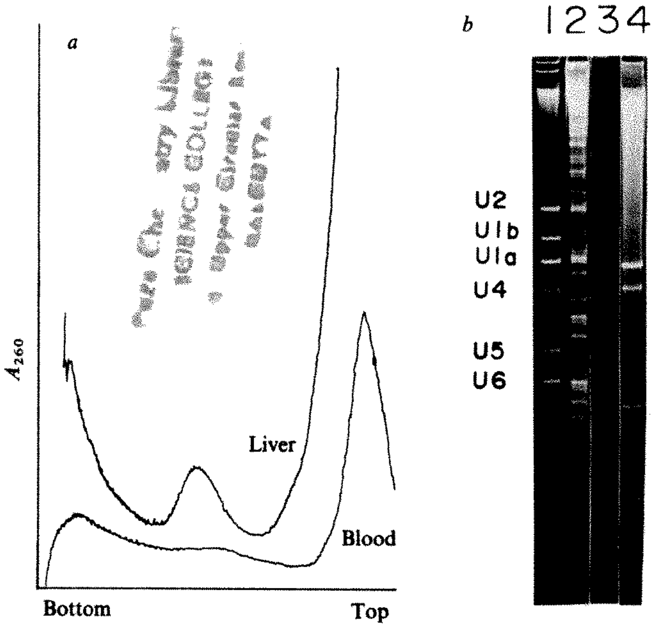

Fig. 2 Sedimentation patterns and gel analysis of small RNAs from nuclear extracts of liver and red blood cells of an adult chicken. *a*, Comparable numbers of liver and RBC nuclei (prepared as in refs 18 and 9, respectively) were extracted with *p*H 8.5 buffer[18]. The extracts were applied to 15–30% sucrose gradients and centrifuged for 17 h at 4 °C and 23,000 r.p.m. in an SW 41 rotor. SDS polyacrylamide gel electrophoresis[9] confirmed that the 30S peak contains primarily the prominent proteins of the 30S hnRNP[18-20]. *b*, RNAs obtained by phenol extraction were analysed by electrophoresis as in Fig. 1. Lane 1, marker Ehrlich ascites snRNAs selected by immunoprecipitation with anti-Sm antibody. Lane 2, total RNA from an extract of chicken liver nuclei. Lane 3, total RNA from an extract of an equivalent number of chicken RBC nuclei. Lane 4, total RNA from an extract of chicken RBC nuclei; the amount of extract loaded represents a 25-fold increase in number of nuclei over that shown in lanes 2 and 3.

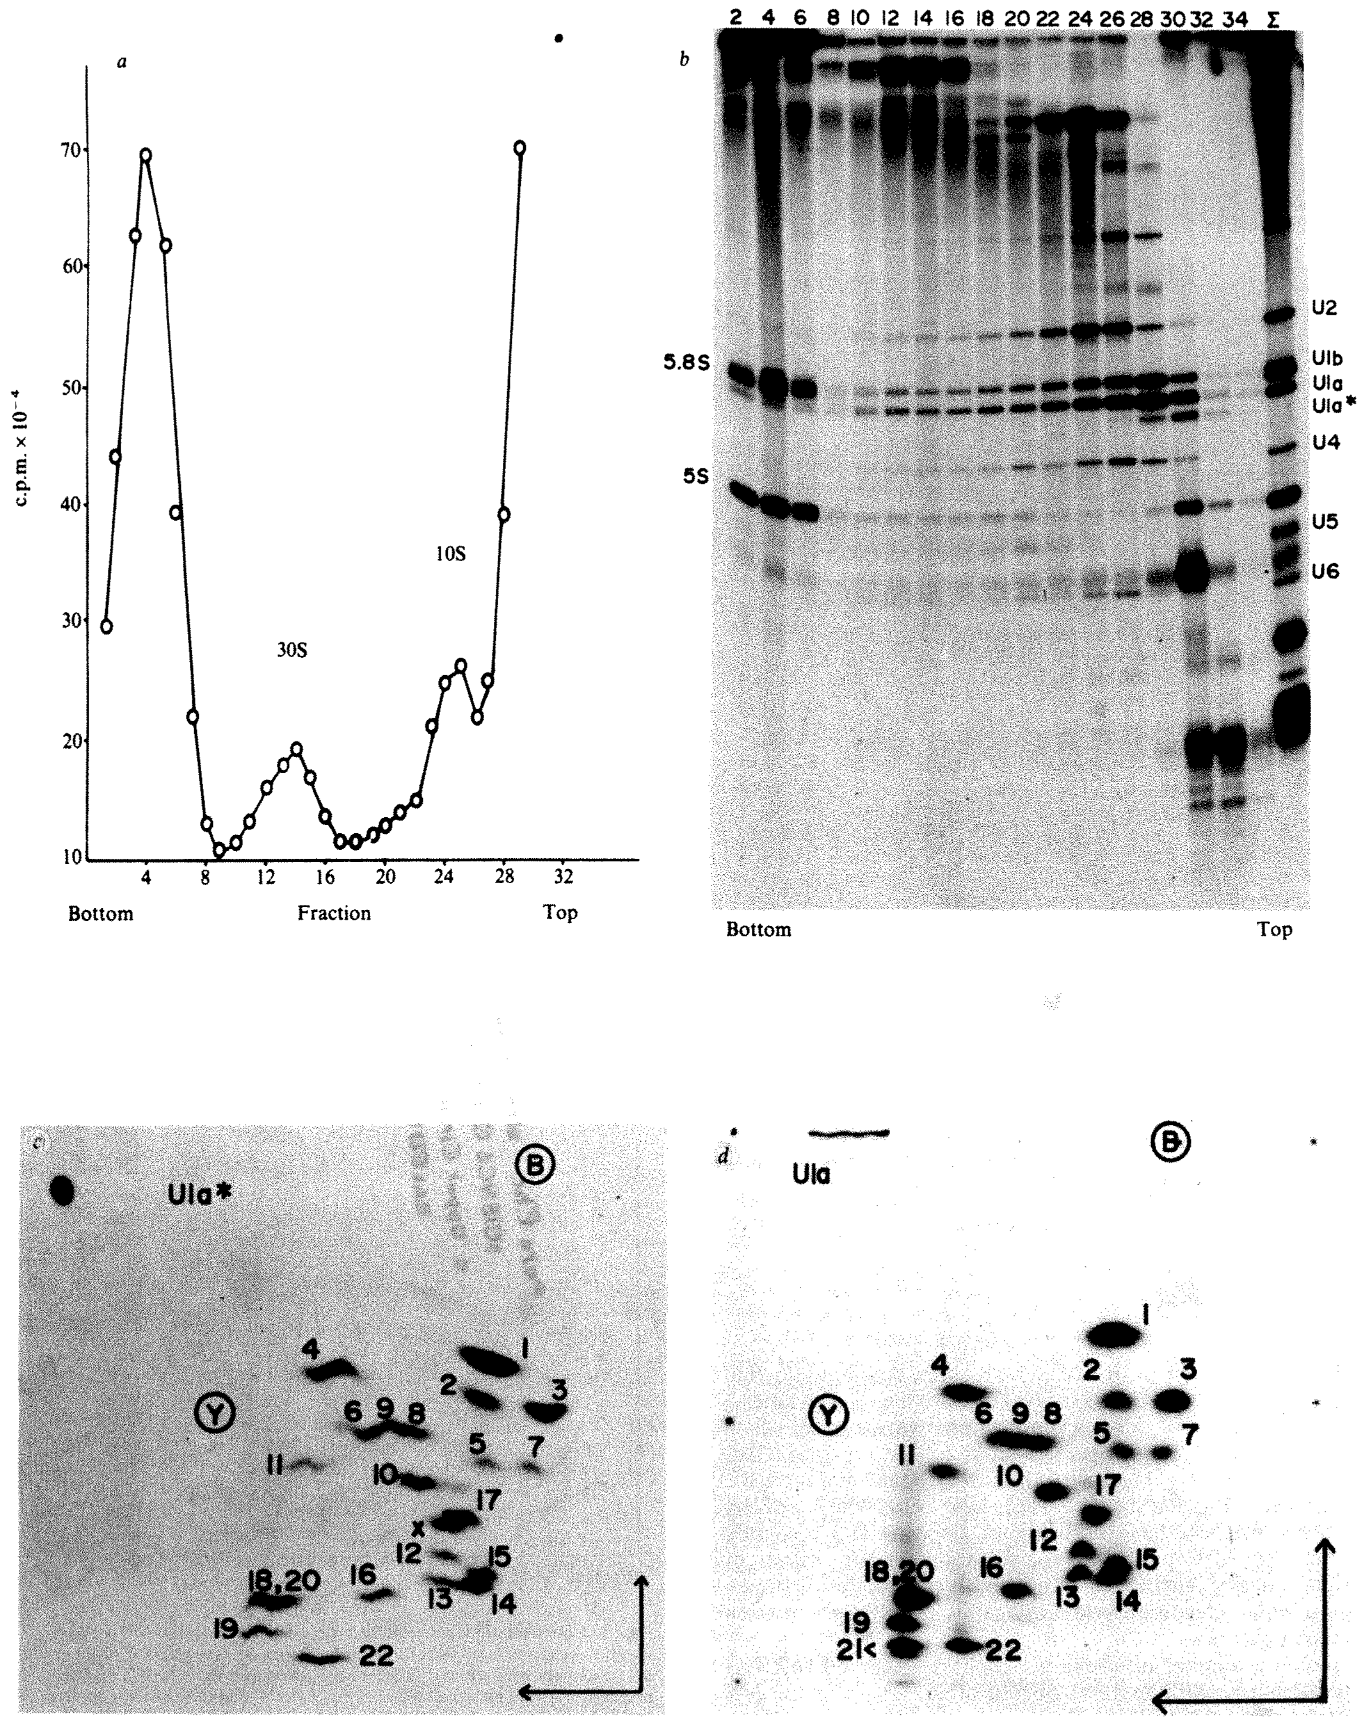

Fig. 3 Location and identification of snRNAs after sucrose gradient fractionation of a nuclear extract. *a*, Nuclei were prepared from ^{32}P-labelled Erlich ascites cells, extracted in high *p*H buffer[9] and the extract applied to a sucrose gradient as in Fig. 2*a*, *b*. The lanes in the gel (run as in Fig. 1) correspond directly to the numbered fractions in the gradient. Direct phenol extraction and prior immunoprecipitation with anti-Sm serum revealed the same distribution of snRNAs. Some contaminating ribosomes appear near the bottom of the gradient, but SDS polyacrylamide gel analysis reveals that the 30,000–40,000 MW 'core proteins'[18–20] of the hnRNP predominate in the 30S region. Indicated RNA species were identified by fingerprint analysis. *c*, T1 RNase fingerprint of U1a. The numbering system corresponds to ref. 7. Ⓑ and Ⓨ indicate the positions of the blue and yellow dyes in first (horizontal) and second (vertical) dimension. Spot 21 is the 5′ end oligonucleotide. *d*, T1 RNase fingerprint of U1a*. Spot X is the remnant of the 5′ oligonucleotide.

Sequences at splice junctions. The 36 'donor' (5′ end) sequences and 37 'acceptor' (3′ end) sequences represent 43 possible splicing events (each event is depicted on a separate line). Underlined sequences are redundant (either because they are identical to a homologous region or because they represent an alternative splice involving the same region) and were not included in our tabulation. Also not included are sequences at late adenovirus mRNA splice junctions as these are proposed to be recognised by VA RNA[26].

* R. Kamen and B. Griffin, personal communication.

† Refs.

can make at least six (usually eight or nine) of the 11 possible base pairs with U1 RNA.

The complementarity of the U1 sequence to splice junctions in mRNA precursors suggests how hnRNA exons separated by an intervening sequence could be brought into proper orientation for splicing. Because U1 RNA is capable of forming Watson–Crick base pairs with a significant number of residues that lie within the two ends of an intron, a single U1-containing snRNP could interact with both junctions simultaneously (Fig. 4*b*). A similar model has been independently proposed suggesting the involvement of an adenovirus-encoded small RNA known as VA in the processing of late adenovirus messages[26]. Although the complementarity between U1 RNA and splice junction sequences is quite striking, the stability of the predicted helices may be insufficient to achieve the fidelity of splicing observed *in vivo*. Thus, it is attractive to invoke RNA·RNA interactions as only one component of the recognition of intron–exon junctions by a particle containing both U1 RNA and proteins.

Fig. 4 Possible base-pairing interactions between U1 and splice junction consensus sequences. The U1 sequence is from ref. 7. Sequences used to generate the consensus sequences are presented in Table 1. *a*, To appear in the 5′ or 3′ consensus splice junction sequence, a base must be the most common in that position and occur with a frequency of at least 45%; bases occurring in 75% of the sequences are underlined; those present with 95% or greater frequency are underlined twice. In the position marked $^{A}_{C}$, A occurs 11 times and C 10 times in the 26 unique sequences examined. Y indicates pryimidines. X marks the location of a single nonconserved base in the 3′ consensus sequence. Vertical lines show the most likely location of the splice. The arrow locates the 5′ end of U1a*. All bases occurring with a frequency of 45% or greater are shown. *b*, A possible model for alignment of intron–exon boundaries by base pairing between U1 RNA and sequences at both ends of an intron.

In summary, the abundance of U1 RNA in active cells (about 10^6 per nucleus), the high conservation of both its sequence and the proteins with which it associates, and its considerable complementarity to splice junctions are all consistent with the idea that U1-containing snRNPs have a key role in eukaryotic mRNA processing. They could either be the splicing enzyme itself (note the example of *E. coli* RNase P, which contains a small RNA complexed with several small proteins[27]) or an auxiliary factor required to align splice junctions. One specific prediction of our hypothesis is that avian and insect U1 RNAs should possess 5′ end sequences similar to mammalian U1 as the splice junction sequences determined for the chicken ovalbumin and silkworm fibroin genes show the same degree of complementarity to mammalian U1 as do mammalian splice junction sequences (see Table 1). Likewise, it should be possible to demonstrate direct interaction between a U1-containing snRNP and splice junction sequences in a particular hnRNA. Finally, the introduction of antibodies into living cells or *in vitro* splicing systems[28,29] may result in the inhibition of one or more specific steps in the RNA processing pathway. Experiments relating to this are now underway.

The fact that the other closely related snRNPs (containing U2, U4, U5, or U6 snRNAs) possess common antigenic determinants suggests that they may function comparably to the U1-containing snRNP in RNA processing; different RNA sequences at their 'active sites' could facilitate more precise recognition of variant splice junction sequences in hnRNA or in other RNA molecules. Alternatively, the additional related snRNPs could participate in the transport of RNA molecules from the cell nucleus, as is suggested by the finding that splicing and export seem to be inseparably linked for those hnRNAs that undergo splicing[30,31]. Whatever the outcome, it seems reasonable to investigate further the proposal[26,32–35] that RNA·RNA interactions provide specificity for the precise editing of eukaryotic transcripts; this possibility seems especially attractive when one considers the central role of base pairing interactions in other essential processes (for example, transcription and translation) that developed at an early stage in evolution.

Plasmid-mediated tissue invasiveness in *Yersinia enterocolitica*

Don L. Zink†¶, James C. Feeley*, Joy G. Wells*, Carl Vanderzant‡, John C. Vickery§, William D. Roof§ & Gerard A. O'Donovan§

*Bureau of Epidemiology, Center for Disease Control, Atlanta, Georgia 30333

Plasmids have an important role in the pathogenicity of certain bacterial species, and *Escherichia coli* provides the most complete example of the relationship involved. Enterotoxigenic strains of *E. coli*, in addition to producing heat-stable and/or heat-labile enterotoxins, may also produce a haemolysin and fimbriate cell surface antigens which facilitate the adherence of the bacterial cell to the mucosa of the small bowel. Numerous studies have shown that these properties are plasmid-mediated[1–5] and that the plasmids act in concert to confer on the host bacterium the ability to produce enteric disease in man and in animals. Moreover, studies with invasive strains of *E. coli* have shown that the Col V plasmid, which codes for the synthesis of colicin V, significantly enhances the pathogenicity of its host bacterium[6,7]. Although the relationship between Col V plasmids and virulence is unclear, reports indicate that Col V-containing strains of *E. coli* are better able to survive in the alimentary tract and that colicine V itself inhibits macrophage function[7,8]. It is probable that bacterial virulence is a complex phenomenon involving both chromosomal and plasmid genes. We describe here a virulence plasmid which mediates tissue invasiveness in human pathogenic strains of *Yersinia enterocolitica*.

Y. enterocolitica is an ubiquitous organism found primarily in the alimentary tract of warm-blooded animals, including man, and in freshwater lakes and streams[9]. Organisms currently regarded as *Y. enterocolitica* are biochemically and serologically heterogeneous[9,10]. Nevertheless, certain biochemical and serological types of the organism are consistently associated with acute gastroenteritis and mesenteric lymphadenitis in man[9]. *Y. enterocolitica* serotypes 0:3 and 0:9 are the most common cause of human infection in Europe, Japan and Canada, whereas serotype 0:8 strains are responsible for infections in the United States[9]. Most strains of *Y. enterocolitica* associated with human infection produce a heat-stable enterotoxin (ST) and demonstrate tissue invasiveness as determined by penetration of cultured mammalian cells or by invasion of the conjunctival epithelium of guinea pigs (Serény test)[11–14,19,20].

We examined the role of plasmids in the virulence of a group of serotype 0:8 strains of *Y. enterocolitica*, obtained during an epidemiological investigation of an outbreak of enteric disease involving 218 school children in New York who had consumed contaminated chocolate milk[15]. The group was interesting because it represents epidemiologically related tissue-invasive and non-tissue invasive strains that are otherwise serologically and biochemically identical. We also examined strains isolated from the incriminated chocolate milk, asymptomatic persons, dairy cattle and water collected from a dairy farm. Those from the latter three sources either did not belong to serotype 0:8 and were believed to be unrelated to the disease outbreak: they were included for comparison with the human-pathogenic serotype 0:8 strains. Each strain was examined for heat-labile toxin (LT) and heat-stable toxin (ST) production, tissue invasiveness (TI) and plasmid DNA content.

A summary of the results of this examination as well as the source of each strain is given in Table 1. No strains produced LT

¶ To whom correspondence should be addressed.

whereas ST production was common. Only serotype 0:8 strains could invade tissue. Serotype 0:8 strains contained either a 41×10^6 or both, whereas other strains either did not contain plasmid DNA or they contained plasmids with other molecular weights (Fig. 1). These results suggest that tissue invasiveness is related to the 41×10^6-MW plasmid, because all invasive strains contain the 41×10^6-MW plasmids; in addition, the 41×10^6-MW plasmid is not found in non-invasive strains. There was no apparent relationship between plasmid DNA and ST production. Because most strains of *Y. enterocolitica* produce ST, it is possible that ST production is encoded by chromosomal genes[19,20].

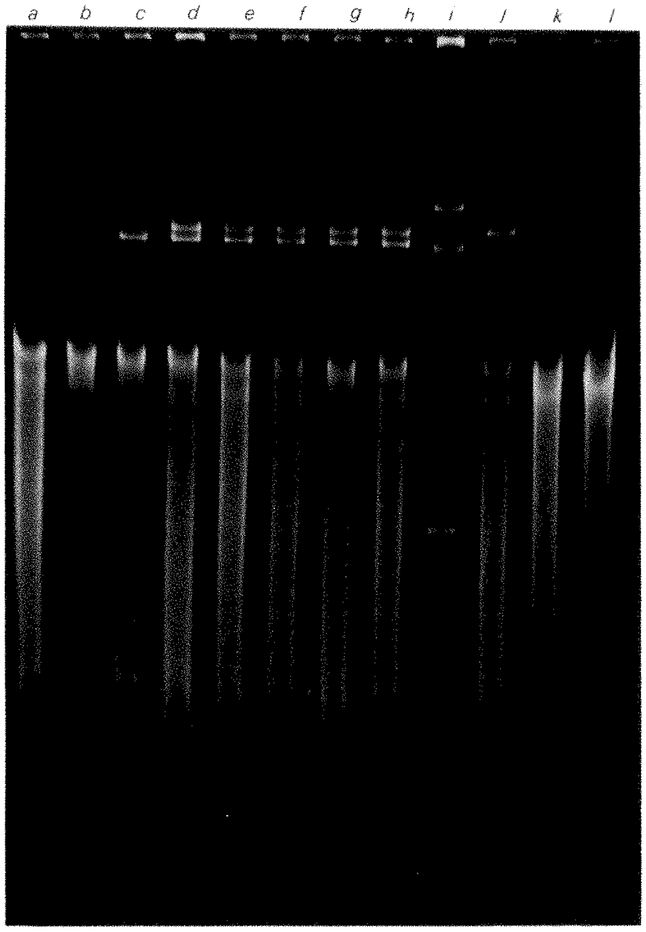

Fig. 1 Identification of plasmid DNA in strains of *Y. enterocolitica*. Partially purified plasmid DNA was isolated from strains of *Y. enterocolitica* and subjected to electrophoresis in 0.7% agarose according to the procedure of Meyers *et al.*[24]. Electrophoresis was carried out at 120 V (31 mA) for 3 h through a 15 cm × 9.6 cm × 0.6 cm gel. After electrophoresis, the gel was stained for 30 min by immersion in electrophoresis buffer (89 mM Tris base, 2.5 mM Na_2 EDTA, 89 mM boric acid) containing 1 μg ethidium bromide per ml. After staining, the gel was rinsed for 1 h under gently running tapwater. The gel was observed and photographed through an orange filter with illumination from a shortwave UV transilluminator. Tracks are as follows: *a*, strain 62, 18 μl partially purified DNA; *b*, strain 61, 18 μl partially purified DNA; *c*, strain 60, 12 μl partially purified DNA; *d*, strain 59, 12 μl partially purified DNA; *e*, strain 58, 12 μl partially purified DNA; *f*, strain 57, 12 μl partially purified DNA; *g*, strain 56, 12 μl partially purified DNA; *h*, strain 55, 12 μl partially purified DNA; *i*, purified standard plasmid DNA (10 μl): upper band, R6-5 (MW 65×10^6); second band, RP4 (MW 34×10^6); third band, S-a (MW 23×10^6); fourth band, pMB9-trimer (MW 10.5×10^6); fifth band, pSC101 (MW 5.8×10^6); sixth band, ColEl (MW 4.2×10^6); *j*, strain 54, 12 μl partially purified DNA; *k*, strain 53, 18 μl partially purified DNA; *l*, strain 63, 18 μl partially purified DNA.

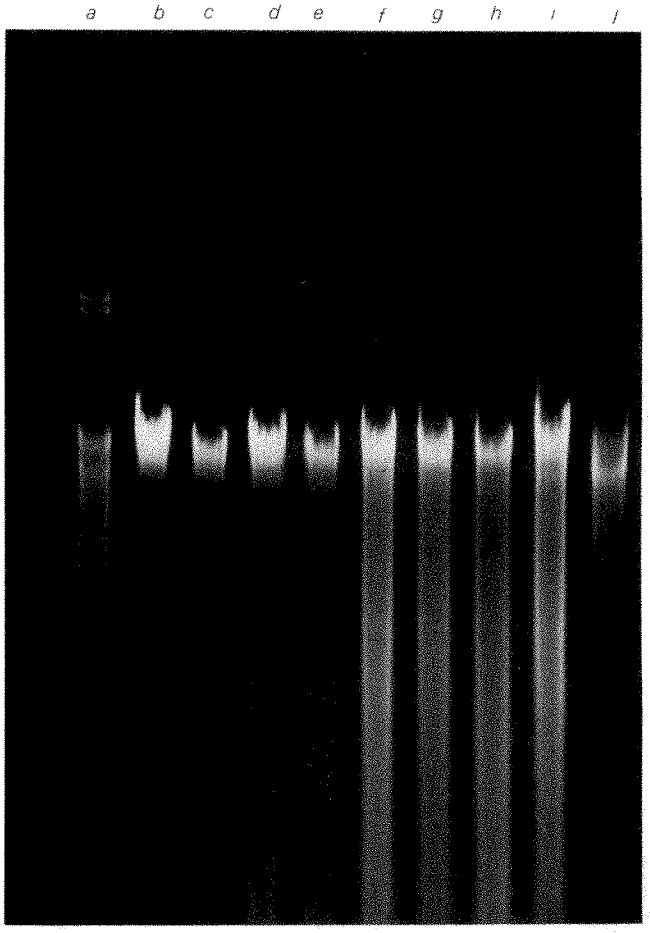

Fig. 2 Agarose electrophoresis of DNA from ethidium bromide-cured strains derived from strain 54. Partially purified plasmid DNA was prepared and electrophoresed as described in Fig. 1. Tracks are as follows: *a*, strain 58, 12 μl partially purified DNA; *b–i*, 25 μl partially purified DNA from eight independently isolated strains derived from strain 54 by curing with ethidium bromide at 35 °C; *j*, strain 60, 12 μl partially purified DNA.

In an effort to confirm the relationship between tissue invasiveness and the 41×10^6-MW plasmid, we grew strains 54 and 58 at 35 °C in the presence of the DNA-intercalating dye, ethidium bromide, which is known to inhibit the replication of some plasmids[21]. Single colony isolates, which had arisen from bacteria grown in the presence of ethidium bromide, were tested for ST production and the presence of plasmid DNA. Isolates derived from strain 54 after curing with ethidium bromide no longer contained plasmid DNA (Fig. 2) and were no longer tissue-invasive. Isolates derived from strain 58 after curing with ethidium bromide now contained only the 35×10^6-MW plasmid (Fig. 3) and were no longer tissue-invasive. Even after repeated subculture, the cured strains did not regain the ability to invade tissue. The 41×10^6-MW plasmid could not be detected in the cured strains by either agarose gel electrophoresis or ethidium bromide-caesium chloride buoyant density ultracentrifugation. We found that the 41×10^6-MW plasmid could be cured from strains 54 and 58 simply by growing them at 35 °C. Table 2 summarises the results of these curing experiments. From these data, it is clear that the 41×10^6-MW plasmid is efficiently cured simply by growing the host strain at 35 °C. These experiments confirm a relationship between tissue invasiveness and the 41×10^6-MW plasmid because loss of the plasmid was always accompanied by loss of tissue invasiveness, regardless of the curing procedure. These results explain earlier observations that some strains of *Y. enterocolitica* lose the ability to invade tissue when grown at 35 °C (refs 11, 14).

When 41×10^6-MW plasmid-cured derivatives of strains 54 and 58 were tested for the ability to produce ST, those treated at 35 °C with ethidium bromide had become temporarily ST negative, while 35 °C alone had not affected ST activity. ST negative strains usually regained ST activity after repeated subculturing.

This further supports the hypothesis that ST production in *Y. enterocolitica* is encoded by chromosomal genes.•

One of the serotype 0:8 strains, strain 60, was isolated from a symptomatic child, yet lacked both the plasmid of MW 41×10^6 and the ability to invade tissue, possibly because this strain was subcultured at 37 °C before inclusion in our study. The other strains used were not subcultured above 26 °C. Strain 54, a tissue-invasive isolate from the incriminated chocolate milk contains only the plasmid of MW 41×10^6. Presumably, the contaminated chocolate milk could have contained as many as four different types of serotype 0:8 *Y. enterocolitica*: those containing no plasmid DNA, those containing both the 35×10^6-MW and 41×10^6-MW plasmids, and those containing either of the two plasmids. We believe that a strain containing both plasmids was responsible for the disease outbreak, because such strains were isolated independently from the faeces of several symptomatic individuals. At this time, it is not known if the plasmid of MW 35×10^6 has a role in human pathogenicity, however, the plasmid of MW 41×10^6 is clearly associated with tissue invasiveness as determined by the Serény test.

We believe this is the first report of a plasmid that mediates tissue invasiveness in a member of the Enterobacteriaceae. These plasmids may also be present in other enteric pathogens, notably *E. coli* because *Y. enterocolitica* and *E. coli* are known to exchange plasmid DNA[22,23]. Furthermore, this report serves to illustrate the value of a molecular and genetic characterisation of plasmid DNA in bacteria isolated during an epidemiological investigation.

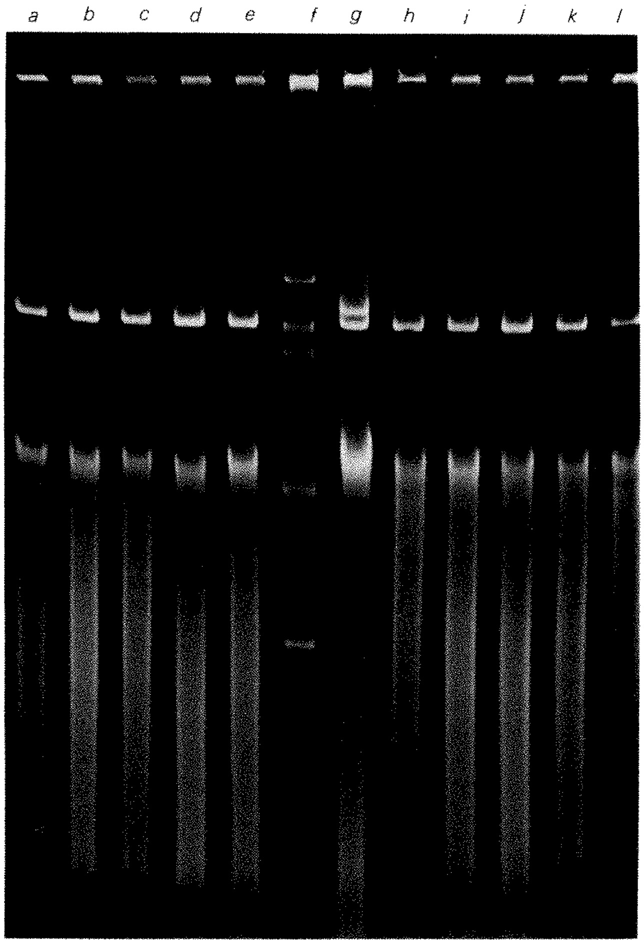

Fig. 3 Agarose electrophoresis of DNA from strains derived from strain 58 by curing with ethidium bromide. Partially purified plasmid DNA was prepared and electrophoresed as described in Fig. 1. Tracks are as follows: *a–e* and *h–l*, 25 µl partially purified DNA from 10 independently isolated strains derived from strain 58 by curing with ethidium bromide at 35 °C; *f*, purified standard plasmid DNA (10 µl) as described in Fig. 1; *g*, strain 58, 25 µl partially purified DNA.

Functional and molecular organisation of an antigen-specific suppressor factor from a T-cell hybridoma

Masaru Taniguchi & Izumi Takei

Tomio Tada

Department of Immunology, Faculty of Medicine, University of Tokyo, Japan

Thymus-dependent (T) lymphocytes have been shown to have antigen specificity. The antigen receptor on T lymphocytes, in contrast to that on B lymphocytes, does not appear to be of the conventional immunoglobulin (Ig) type. Studies on the antigen-specific factors derived from helper and suppressor T cells (Ts) demonstrated that they possess determinants with antigen binding affinity and products of genes in the H-2 complex (MHC)[1–6]. Furthermore, antibodies against the variable region of Ig heavy chains or idiotypes have been shown to react with T-cell antigen receptors as well as antigen-specific helper and suppressor T-cell factors (TsF)[7–15]. It is, therefore, conceivable that at least two gene products are involved in the structural entity of these receptors: one each coded for by genes in either. To establish the molecular nature of the recognition component of T cells we have used homogeneous TsF from a T-cell hybridoma with a specific function. We report here that the antigen binding and I-J coded molecules on TsF are independently synthesised in the cytoplasm, and are secreted as an associated form of the two molecules; this association is required for antigen-specific suppression of antibody response.

Table 1 Presence of the associated and non-associated forms of antigen-binding and I-J coded molecules in the extract and lack of the non-associated form in ascites

Materials added to the culture	Anti-DNP IgG PFC per culture Ascites	Extract
None	1,774 ± 182	1,211 ± 269
Unabsorbed	313 ± 75	146 ± 113
Absorbed with anti-Igs	462 ± 164	131 ± 193
Eluted from anti-Igs	1,802 ± 440	1,547 ± 172
Absorbed with KLH	2,236 ± 174	1,255 ± 465
Eluted from KLH	668 ± 237	219 ± 170
Absorbed with anti-I-J^b	2,043 ± 258	1,342 ± 21
Eluted from anti-I-J^b	580 ± 128	131 ± 193
Combination of materials absorbed with KLH and anti-I-J^b	2,118 ± 335	100 ± 94

The secreted or extracted materials were obtained from suppressor T-cell hybridoma as described previously[16]. Briefly, the hybrids were made by fusion of AKR thymoma cell line BW5147 with the enriched suppressor T cell of C57BL/6 mice specific for KLH. For hybridisation, 5×10^6 enriched suppressor T cells of C57BL/6 origin and 5–50×10^6 BW5147 cells were washed twice in serum-free Dulbecco's modified Eagle's medium (DMEM) and pelleted together at 400 *g*. Polyethylene glycol (2 ml: PEG, molecular weight 2,000)–dimethyl sulphoxide (DMSO) solution (1 weight of PEG plus 1 volume of 15% DMSO–DMEM) was added to the cell pellet and mixed gently. A further 2 ml of 50% (W/V) PEG solution without DMSO was poured into the test tube and the mixture was gently stirred with a Pasteur pipette. The cell suspension was then gradually diluted with 16 ml of serum free DMEM and further diluted with 180 ml of DMEM containing 13% fetal calf serum (FCS). It was then incubated at 37 °C for 3–4 h in 5% CO_2. After incubation cells were washed four times with DMEM and cultured for 1–2 weeks in HAT medium (RPMI 1640 supplemented with 10% FCS and hypoxanthine, aminopterin, thymidine (HAT)) on Falcon plates (Falcon 3008).Cells grown in HAT medium were collected and stained with anti-I-J^b anti-serum (B10.A(5R) anti-B10.A(3R)) and fluorescein-conjugated rabbit anti-mouse Igs. The stained cells were then sorted by fluorescence-activated cell sorter, FACS II (Becton-Dickinson), and I-J positive cells were cloned in a multiwell microplate (Falcon 3040) by limiting dilution or single cell manipulation. So far we have established several I-J positive suppressor T-cell hybridomas with specific functions, that is, cell lines 34S-704, 34S-18, 34S-11, 1L-1, 8C-23, and 9F-18, each of which has the same characteristics as the cell line 9F181a described previously[16]. The cell-free extract used was obtained by ultracentrifugation of the frozen and thawed materials of the hybrid cells (34S-704) at 20,000*g* for 1 h, and the secreted materials were obtained in ascites of hybridoma (34S-704)-bearing F_1 mice. 20 μl of ascites or extracted materials from 3×10^5 hybridoma cells were passed through the immunoadsorbents composed of KLH (5 mg per ml of beads), anti-I-J^b (B10.A(5R)anti-B10.A(3R); 1 ml γ-globulin fraction of antiserum per ml of beads), rabbit anti-mouse Igs (5 mg purified anti-mouse Ig antibodies per ml of beads). The beads used were Sepharose 4B prepared as described previously[16]. The materials absorbed by columns were eluted with 0.175M glycine–HCl buffer *p*H 3.2 followed by an instant neutralisation with 1 M sodium bicarbonate, dialysed for 4–6 h with 0.01 M sodium phosphate-buffered saline *p*H 7.2 and concentrated by negative pressure. The effluents and the eluates from the columns, and the mixture of the effluents from each column were added to the culture of 4×10^6 spleen cells of C57BL/6 mice primed with 100 μg DNP–KLH plus 1×10^9 pertussis vaccine in the Mishell-Dutton system (Falcon 3008 plate), in 1 ml RPMI 1640 enriched with 10% FCS in the presence of 0.1 μg DNP–KLH and 2.0×10^{-5}M 2-mercaptoethanol. Anti-DNP IgM and IgG PFC were assayed on day 5 of culture by the method of Cunningham and Szenberg as described previously[3]. Results are expressed as mean numbers of anti-DNP IgG PFC of four cultures ±s.d.

The T-cell hybridomas with specific suppressive activity were established 20 months previously by the fusion of BW5147 (H-2^k) and enriched Ts of C57BL/6(H-2^b) mice primed with keyhole limpet haemocyanin (KLH). The hybrids continuously secrete specific suppressor molecules with an antigen binding site and products of genes in the I-J subregion of MHC. The properties and functions of the hybridoma-derived TsF have been reported previously[16]. We attempted to separate the active moiety so as to characterise further the structure of the hybridoma-derived TsF. The suppressive extract or ascitic material from the hybridoma (34S–704) was passed through immunoadsorbent columns of KLH, anti-I-J^b and anti-mouse Igs under the same conditions as described previously[16]. The absorbed materials were eluted from columns with glycine–HCl buffer, *p*H 3.2 at 0 °C. Both effluents and eluates were tested for their suppressive activity. As shown in Table 1, the activity of TsF from the hybridoma was absorbed by KLH and anti-I-J^b columns but not by the anti-Igs. The activity was successfully recovered in the acid eluate from KLH and anti-I-J^b columns. These results indicate that TsF in the extracted and secreted materials has both antigen-binding sites and I-J determinants, and can be recovered from either the KLH or anti-I-J^b column. These two determinants are also demonstrated on the surface of semipurified Ts[15,17] and hybridomas[18]. In contrast, recent reports[9,10] showed that isolated T-cell receptor molecules do not contain detectable MHC gene products. It is, therefore, of interest to determine whether or not the I-J determinant is in fact associated with antigen-receptor of Ts, and if such association is indeed required for suppression. If these two distinct determinants are present on a single molecule, the mixture of the materials after absorption with the KLH or anti-I-J^b column should not exert any suppressive activity. On the other hand, if they are on separate molecules and combine when they act on target cells, the mixture should reconstitute the suppressor activity. The mixture of the effluents of ascites from the KLH and anti-I-J^b columns gave no suppressive effect (Table 1). Unlike ascites, the mixture of the effluents of the extracted material definitely produced a strong suppression, despite the fact that either effluent alone had no detectable activity. These

0028-0836/80/020227—02$01.00

results indicate that the extract, but not ascites, contains two discrete molecules which would combine to reconstitute suppressor activity. Associated forms of suppressor molecule, however, should be present in the extract, since the activity could be eluted from either KLH or anti-I–J^b column. The secreted material, however, contains only molecules of the associated form.

These experiments do not, however, exclude the possibility that the suppressor activity in the mixture of the two effluents is caused by the additive effect of residual TsF remaining after absorption, even though the effluents alone did not exert detectable suppressor effects. To eliminate this possibility, the extract was passed through the KLH or anti-I–J^b column (first column), and the effluent from each of the columns was successively applied to both KLH and anti-I–J^b columns (second column) (Fig. 1). The effluent from either the KLH or anti-I–J^b column was tested directly for its suppressive activity. In other experiments, the effluent from the KLH column was reabsorbed with another KLH column to ascertain complete absorption. Similar double absorption tests were performed with anti-I–J^b column. The effluents, each after absorption twice with the KLH or anti-I–J^b column were admixed and tested for the suppressor activity. As shown in Table 2, the suppressive activity in the extract was abrogated by absorption with the KLH or anti-I–J^b column (group III or IV). However, the mixture of the KLH→KLH effluent and anti-I–J^b→anti-I–J^b effluent (group V) showed strong suppressor activity. Effluent from the KLH double columns should not contain KLH-binding molecules while I–J molecules are still present. Similarly, after absorption twice with the anti-I–J^b column, I–J molecules are completely removed leaving KLH-binding molecules in the effluent. Hence, the combination of these two effluents resulted in the mixture of the two molecules which reconstituted the suppressive activity. On the contrary, no suppressive activity was recovered when the effluent from the KLH (or anti-I–J^b) column was successively absorbed with the anti-I–J^b (or KLH) column (the mixture of KLH→anti-I–J^b effluent and anti-I–J^b→KLH effluent; group VI). These results suggest that antigen-binding and I–J coded molecules are present independently in the extract, and the association of these two molecules, either of which has no detectable activity by itself, reconstitutes the suppressive activity. Although we have not excluded the possibility that the non-associated form in the extract is due to an inbalance in the synthesis of the two molecules in hybridoma cells, it is concluded that there are at least three molecules in the extracted material: antigen-binding molecule, I–J coded molecule and the associated form of the two molecules. The secreted material consists of the associated form alone. It is, therefore, likely that the two independent molecules in the extract are synthesised in the cytoplasm as a precursor of the suppressor factor which is then secreted after the association.

Our previous studies showed that KLH–TsF specifically suppresses the response of histocompatible spleen cells but not that of allogeneic cells[19]. This genetic restriction is governed by genes in the I–J subregion. The hybridoma-derived TsF also showed rigid genetic restriction[16]. In agreement with this antigen specificity and H-2 restriction of TsF, our present results show firm evidence that the functional structure of TsF is composed of two distinct molecules; one involved in the specific antigen-binding molecule, probably having V_H structure and the other the I–J coded molecule which may serve as a restricting element in the suppressor cell interaction. A definitive answer must await chemical and physiochemical analysis of the hybridoma-derived suppressor molecule.

This work was supported by a grant from the Ministry of Education, Culture and Science, Japan.

Table 2 Requirement of the co-existence of I–J bearing and antigen-binding molecules for the manifestation of suppressor function

Experimental group	Materials after absorption with: first column	→ second column		Anti-DNP IgG PFC per culture
I	None			2,824 ± 98
II	Unfractionated			525 ± 196
III	KLH	None		1,722 ± 224
IV	Anti-I–J^b	None		2,923 ± 598
V	KLH	→ KLH	combined	383 ± 150
	Anti-I–J^b	→ Anti-I–J^b		
VI	KLH	→ Anti-I–J^b	combined	2,507 ± 287
	Anti-I–J^b	→ KLH		

The extracted materials (34S-704) unabsorbed (group II), absorbed with the KLH (group III) or anti-I–J^b (group IV) column, or the mixture of the effluents from the double columns (groups V or VI) as indicated in Fig. 1 were added to the culture of DNP–KLH primed spleen cells from C57BL/6 mice and tested for their suppressive activity. The assay of anti-DNP IgG PFC is the same as in Table 1. Results are expressed as mean numbers of anti-DNP IgG PFC of four cultures ±s.d.

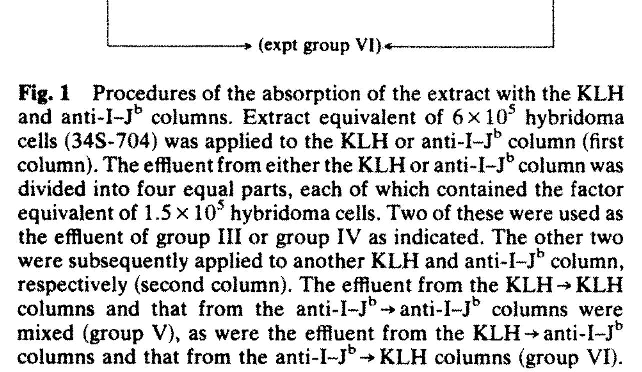

Fig. 1 Procedures of the absorption of the extract with the KLH and anti-I–J^b columns. Extract equivalent of 6×10^5 hybridoma cells (34S-704) was applied to the KLH or anti-I–J^b column (first column). The effluent from either the KLH or anti-I–J^b column was divided into four equal parts, each of which contained the factor equivalent of 1.5×10^5 hybridoma cells. Two of these were used as the effluent of group III or group IV as indicated. The other two were subsequently applied to another KLH and anti-I–J^b column, respectively (second column). The effluent from the KLH→KLH columns and that from the anti-I–J^b→anti-I–J^b columns were mixed (group V), as were the effluent from the KLH→anti-I–J^b columns and that from the anti-I–J^b→KLH columns (group VI). The unabsorbed (group II), the absorbed (groups III and IV) or the mixture of the effluents absorbed with double columns (groups V and VI) were added to the culture and their suppressive activities were tested in comparison to the response of group I without the factor. The materials of each group should contain the factor equivalent of 3×10^5 hybridoma cells.

Dioxin as a health hazard

Alastair Hay

VIETNAM and Sev́eso are the two principal subjects in this book on dioxin contamination. Vietnam had about 100 kg of 2, 3, 7, 8 — tetrachlorodibenzo-p-dioxin (dioxin) dumped on it in the course of the US military defoliation programme over the country from 1962-1970. Sev́eso, a small Italian town some fifteen miles north of Milan, was also the hapless victim of dioxin when in July, 1976, a reactor manufacturing trichlorophenol overheated. The reactor contents, including some 1-1.5 kg of dioxin, were vented into the atmosphere and precipitated out over the town and its environs.

The author of this book quite clearly chose Vietnam and Sev́eso to make the point so aptly summarised in the title. It is Whiteside's thesis that contamination of the environment by dioxin poses a considerable health hazard, and that time to deal with it may be running out.

Much of the material in this book is not new and was first published as two long articles in the *New Yorker.* Whiteside is a staff writer for the magazine and his book is written in the same relaxed style which is a characteristic of this American weekly. The result is that the message is hammered home, all the harder; Whiteside is out to convince readers of the dangers posed by dioxin.

The narrative begins with Vietnam and the military defoliation programme during which over 11.0×10^6 gallons of the herbicide Agent Orange (a 1:1 mixture of 2,4,5-trichlorophenoxyacetic acid (2,4,5-T) and 2,4-dichlorophenoxyacetic acid) was sprayed on forests and food crops. This, however, is history. What concerns Whiteside is the fact that 2,4,5-T is still used in the United States. It is 2,4,5-T which contains the dioxin contaminant, carried over from an earlier step in the manufacturing process when trichlorophenol is produced. And dioxin is now known to be a teratogen, mutagen and carcinogen.

The Pendulum and the Toxic Cloud: The Course of Dioxin Contamination. By Thomas Whiteside. Pp. 205. (Yale University Press: New Haven, Connecticutt, and London, UK, 1979.) £10.80.

Lessons learned in Vietnam about the havoc caused by the herbicides are used by the author to illustrate the risks entailed by the continued use of 2,4,5-T. There are parallels between 2,4,5-T use in Vietnam and in the US, but there is one important difference. The concentration of dioxin present in 2,4,5-T in the US is probably about 1/100th of that used in Vietnam. Curent formulations of 2,4,5-T contain less than 0.1 p.p.m. of dioxin. There are those who argue, however, that even this concentration is high enough to present a health risk. Whiteside takes the same view.

The US Environmental Protection Agency (EPA) is also concerned about 2,4,5-T and in March this year issued a banning order restricting its use. According to the EPA there is a correlation between 2,4,5-T spraying of forests in the state of Oregon and an increase in the rate of spontaneous abortions in the area. The EPA announcement came too late for inclusion in Whiteside's book, nevertheless, the author has captured the changing mood in the US about the wisdom of using 2,4,5-T. In an enlightening anecdote, he reports that "The attitude toward 2,4,5-T has somewhat changed at the Department of Defense it seems. The days are over when during the height of herbicidal operations in Vietnam, an American military spokesman could declare that the relevant herbicidal agents were "not at all harmful to humans or animals" — and illustrate this statement by dabbing on his tongue a bit of liquid from a bottle that sat on his desk".

Sev́eso is a familiar enough story to readers of *Nature.* When the reactor in the ICMESA chemical plant at Sev́eso overheated discharging its toxic contents over the surrounding countryside, it caused one of the most serious pollution incidents yet recorded. It also caught the Italian authorities unprepared. Whiteside cites the illogicality of some of the early restrictions on movement of people into and out of the most seriously contaminated zone (Zone A), at Sev́eso. The authorities, according to Whiteside, "First forbade all entry into it [Zone A] by outsiders and then changed the rules to allow ten persons to enter on weekdays and twenty on Sundays". "When people in the area heard about these safety measures, some of them just laughed, in spite of the tragedy they were caught up in," one person familiar with the evacuation told me. "They would say to one another, 'so dioxin is twice as dangerous on weekdays as it is on Sundays?'."

Although the Italian authorities perhaps deserved the censure they have received, it should not be forgotten that it was a reactor owned by Givaudan — a Swiss multinational and subsidiary of the giant pharmaceutical company F. Hoffmann La Roche — that caused the accident. Givaudan have always insisted that their reactor design was adequate to meet with foreseeable accidents. Perhaps Sev́eso was unforeseeable. But it happened, and the reactor design did not meet the situation.

The author does not deal in great detail with the reactor design, preferring instead to concentrate on the consequences of its failure. Whiteside has interviewed many of the scientists and politicians involved with the aftermath of Sev́eso. Few of them stand out as luminaries. Many of them revealed their party political interest — a loyalty which inhibited the work of the committees concerned with the decontamination and health surveillance programme.

Much of Whiteside's story is concerned with the residents of Sev́eso. Many lost their livelihood; most received compensation for this loss, but the bitterness still lingers and it comes through in this book.

There are a few points which could give the account a slightly different balance. The author has on several occasions been too selective in his choice of material. For example, there are three studies which now show 2,3,7,8-tetrachlorodibenzo-p-dioxin to be carinogenic. Two of these agree on the dose level at which dioxin exhibits its carcinogenic effect, the third predicts the chemical to be a carcinogen at dose levels several orders of magnitude lower. Whiteside only publicises the latter. Then there is the case of the link in several Swedish hospitals between hexachlorophene (a bacteriacide made from trichlorophenol) use and birth malformations. The author retells this story, but omits to mention that it has not been confirmed, and that the Swedish Health Authority is sceptical about the link.

There is an error in the description of the effect of the 1968 explosion in the trichlorophenol reactor at the UK company, Coalite and Chemical Products Ltd. Whiteside says several workers died after the accident as a result of severe liver damage. This is not the case. Only one worker died, and this was as a direct result of injuries received when the reactor blew up. In Europe, however, workers formerly employed on trichlorophenol reactors have died, but so far there is no firm evidence to link these deaths with dioxin exposure.

Apart from these criticisms the book makes good reading. It ought to be read by everyone concerned with how relations between the general public and government authorities can go wrong. But the picture is neither as black, nor as clear cut as the author makes out. There are many questions about dioxin still to be answered. □

Alastair Hay is Lecturer in the Department of Chemical Pathology at the University of Leeds, UK.

Hippocampal function

T.V.P. Bliss

The Hippocampus as a Cognitive Map. By J. O'Keefe and L. Nadel. (Clarendon/Oxford University Press: Oxford, 1978.) £25.

THE hippocampus, a phylogenetically primitive cortical structure long admired by neuroanatomists for the simplicity and regularity of its neural architecture, came to more general notice in the 1950s with the discovery that a bilateral lesion of the hippocampus in man causes severe impairment of memory. This glimpse of the engram aroused great excitement and for the past two decades rats with hippocampal lesions have been among the commoner experimental species in behavioural laboratories around the world. Disappointingly, the benefits of all this effort have not been startlingly apparent. What differences in behaviour can be found between normal and hippocampal rats cannot easily be explained in terms of simple loss of memory. Alternative concepts, such as inhibition and frustration, emerged as candidates for a theory of hippocampal function, but to no very general acclaim. For a time there was a vogue for Keating's hypothesis which allocated to the hippocampus the task of preventing the neocortex from falling into the lateral ventricle and drowning. Meanwhile, and particularly in the past decade, workers from the other end of the neurobiological spectrum — anatomists, physiologists and pharmacologists — have found in the hippocampus a uniquely convenient model for studying synaptic organisation and function in the mammalian cortex, with the result that there is today probably more information, from more sources, about the hippocampus than any other structure in the mammalian brain.

It is an appropriate time therefore for a new look at the problem of hippocampal function. What is needed is a theory which tells us not only what the hippocampus does but also how it does it. This is what O'Keefe and Nadel set out to achieve in their ambitious and stimulating book. According to their theory, the hippocampus is the chartroom of the brain's navigational system, the repository where neural representations of an animal's environment are assembled and stored. The theory derives from the discovery by O'Keefe and Dostrovsky in 1971, that there exist 'place' neurones in the rat's hippocampus which fire only when the animal is at a particular place in the environment; and from a reassessment of the behavioural literature which allows the authors to conclude that it is only in situations where an animal has to identify a place, that hippocampal animals show deficits in behaviour.

The book opens with a discussion of post-Newtonian ideas about space and continues with an illuminating analysis of the ways in which an animal can find its way around space. O'Keefe and Nadel distinguish between two possible navigational strategies (route hypotheses and place hypotheses) based on the two kinds of space which are represented in the brain: relative space, which is centred on the observer, so that spatial relationships between objects in the environment change as the observer moves; and absolute space, which is non-egocentric and items within which are fixed relative to each other. Absolute space can be represented by a map, the neural representation of which, in O'Keefe and Nadel's theory, is located in the hippocampus.

The second section of the book is concerned with the anatomy and physiology of the hippocampus, and opens with a comprehensive account of the afferent and efferent connections of its two principle cell populations, the granule cells of the dentate gyrus and the pyramidal cells of the hippocampus proper. The rather more selective coverage of hippocampal physiology includes a discussion of the properties of place units and a good account of the mysterious theta waves which can be recorded in the hippocampus of conscious animals during voluntary behaviour such as active exploration. The mechanism responsible for generating theta activity is not well understood, though there is some evidence to support O'Keefe and Nadel's assumption that it plays a role in synchronising the excitability of cell populations in the hippocampus.

The authors then present a model of how the hippocampus might function as a map-generating device. Information about the environment is passed to the granule cells from entorhinal cortex. Each granule cell receives a number of entorhinal fibres, at least two of which, representing some specific combination of sensory stimuli, must be active to fire the cell. The output from each granule cell is fed via synapses *en passage* to a large number of pyramidal cells, whose excitability is modulated by theta waves propagating across the hippocampus as the animal moves through its environment. At a given moment therefore only a proportion of the pyramidal cells receiving impulses from an active granule cell will be at the appropriate phase of theta activity to fire. The set of activated pyramidal cells, each one responding to a particular combination of features in the environment, constitutes the neural representation of place. In order to account for the fact that place units continue to fire if any small subset of the set of stimuli which define the environment is removed, it is assumed that the set of active pyramidal cells become functionally linked together through the strengthening of synaptic connections between them. In the third stage of the model a population of pyramidal cells compares the expected with the perceived environment and fires whenever there is a mismatch, thus providing the trigger for renewed exploration. Although the model makes a valiant attempt to exploit the peculiar characteristics of hippocampal anatomy and physiology, including theta activity and long-term potentiation of synaptic connections, it is nevertheless open to many objections. Much of its anatomical substrate is speculative at best, and in the several hippocampal pathways in which the phenomenon has been demonstrated, long-term synaptic potentiation seems to be a function of activity in afferent fibres alone, rather than of conjoint pre- and post-synaptic activity, as the model requires. A more fundamental objection, and one which the authors don't discuss, is how an animal recognises a familiar place when it is approached from a different direction.

In the third and longest section of the book, O'Keefe and Nadel turn their attention to the behavioural literature, and in particular to the learning ability of rats with hippocampal lesions. Their industry here is overwhelming — there is seemingly nothing which they have not read, tabulated, critically assessed. The various types of behavioural experiment are carefully explained and for the reader without experience of the psychological literature this is an outstandingly good introduction. The conclusion the authors reach at the end of this exhaustive survey is that, in general, and as the theory would predict, behavioural deficits in hippocampal animals only emerge in tasks which the intact animal solves using place hypotheses; even then the hippocampal animal may be able to compensate by using alternative route-type strategies. This distinction between the use of place hypotheses in normal animals and the compensatory use of route hypotheses in hippocampal animals brings a considerable degree of order to a literature rich in apparently contradictory results. Nevertheless, doubts remain. During the course of their review a barrage of analytical ingenuity is directed against experiments which do not at first sight fit the prediction of the theory. The effect of this is ultimately to raise doubts in the reader's mind about the ability of any experiment, whatever its results, to furnish convincing evidence against the theory.

The final section is taken up with a discussion of the amnesia which results from hippocampal lesions in humans. This is a controversial area with no general agreement about the extent to which amnesia is a failure of recall rather than a failure of storage. O'Keefe and Nadel propose that the human hippocampus is reserved for a context-dependent memory system, having a spatial component equivalent to a cognitive map, which is located in the right hippocampus and a verbal component responsible for memory of connected discourse or narrative, which is represented in the form of a semantic map in the left hippocampus. They conclude that while the use of strategies designed to assist recall can often improve the performance of amnesics in context-free tasks, such as memorising word lists, this is not the case for context-dependent memories: here the loss of memory is total and irrecoverable.

Both authors were at one time students of D.O. Hebb, and their book, though it lacks the stylistic charm of Hebb's monograph *Organization of Behaviour*, follows the same tradition in its attempt to fuse neurobiological and behavioural data into a unified theory of function. The verdict on the theory must, at the moment, be 'unproven'. But whether or not the theory survives, O'Keefe and Nadel have in this book provided a solid basis on which the question of hippocampal function can, at last, be sensibly debated; on that account alone their book is a very considerable achievement. □

Nuclear and reactor physics concepts

Malcolm C. Scott

A Guidebook to Nuclear Reactors. By A.V. Nero. (University of California Press: Berkeley, Los Angeles and London, 1979.) Hardback £17.50; paperback £5.95.

ALMOST without exception, nuclear power programmes throughout the world have been subjected to critical, and often hostile, scrutiny. There seems to be no single reason for these examinations; certainly, it is not related to the actual safety record of nuclear power reactors, as most re-appraisals predate the accident at the Three Mile Island pressurised water reactor plant at Harrisburg, Pennsylvania. Rather, the opposition to nuclear power has centered on a number of issues. The first of these is the relationship between nuclear power and the spread of nuclear weapons; the second relates to the problem of radioactive waste disposal and the associated question of whether or not we know enough about the effects of radiation; and the third is concerned not with nuclear power *per se*, but with the role of high technology in society.

To an interested but uninformed spectator some of the confrontations which have occurred must have seemed baffling. However, the worst aspect of this is possibly not the fact that 'experts' frequently hold diametrically opposite views but, rather, the fact that, as it *is* high technology, the whole field of nuclear power and radioactivity is relatively inaccessible. The few books written for the layman are too simplistic to allow an understanding of the issues involved (inasmuch as they are technical rather than sociological or political), whereas the specialist monographs are incomprehensible, assuming a background which the layman does not have. Even for professionals, much of the information required to counter opposition arguments is scattered through the literature, and there has been no single book giving the necessary background technical information across the whole nuclear front.

A Guidebook to Nuclear Reactors was written specifically to try and overcome these problems. It is intended for both the non-technically trained and the professional needing a wide ranging but concise guide to the whole nuclear power field.

The book is divided into four parts. The first, entitled "A General Introduction to Nuclear Reactors", starts by outlining the main features of a nuclear power plant and then goes on to consider the effect which such a system has on its surroundings, in terms of both heat and radioactivity discharges. At the end of this section there is a chapter on accidents, discussing how they can arise and what the consequences may be, and concluding with an introduction to risk assessment along the lines of the American Rasmussen Study.

In the second part there are four chapters, each dealing with a specific reactor type, namely pressurised water reactors, boiling water reactors, heavy water reactors and gas-cooled thermal reactors. Here each chapter has the same format, namely a description of the layout and principal components of each reactor type, followed by a description of auxiliary systems. Next comes a discussion of the safety systems incorporated in the reactor, and there is then consideration of fuel utilisation and reactor operation.

The third section, also of four chapters, starts off by considering the question of uranium resources and then goes on to discuss the rôle of both fast breeder reactors and high conversion efficiency thermal systems. The various nuclear fuel cycles are then outlined in the context of fuel processing, which leads naturally to a chapter on "The Weapons Connection". Finally, in the fourth section, there are three chapters on advanced reactor systems ("Breeders, Near-Breeders and What Not"), the last chapter including a mention of fusion, fission-fusion and accelerator-based nuclear fuel breeding systems.

Let it be said immediately that this is an extremely good book. However, the concentration on reactor systems found in, or of interest to, the United States means that systems in, for example, the USSR, together with our own in Britain, get scant mention ("In addition, England has constructed gas-cooled reactors with carbon dioxide coolant"). There is some repetition, which may have a didactic purpose, and some Americanese ("The style of the book is more informational than argumentative"), though mercifully little.

Nevertheless, faced with the abundance of extremely useful tables and figures, it is churlish to emphasise these faults. For the professional involved in nuclear debates and for the student entering the field this is an invaluable book. However, its value for the layman is likely to be limited by the sheer quantity of information and density of technical terms which, even when explained, need to be absorbed in order to appreciate the text. Nevertheless, as a source of background information for the non-scientist it remains the best book which I have seen, and Anthony Nero deserves credit for trying to raise the level of the so-called 'nuclear debate'. □

Malcolm C. Scott is a Senior Lecturer in the Department of Physics at the University of Birmingham, UK, in charge of the MSc course on the Physics and Technology of Nuclear Reactors.

Transport organ physiology

O.H. Petersen

Membrane Transport in Biology. Vol.IV A and B. Edited by G. Giebisch, D.C. Tosteson and H.H. Ussing. Pp.471; 939. (Springer: Berlin, Heidelberg and New York, 1979.) Two volumes DM296; $162.80.

RECENT progress in the study of transport has been astonishing. This is clear when reviewing the impressive series on *Membrane Transport in Biology,* which has now been brought to an end with volume IV (consisting of two books) dealing with the transport organs. The editor of this last volume, Gerhard Giebisch (Yale), is to be congratulated on providing a number of good chapters written by scientists who are among the leaders in their fields of study. It was also a good idea to have asked Renkin (California) to provide an introductory chapter on transport across capillary membranes. However, while there is no denying the general high quality of the individual contributions, this volume is marred by an unfortunate lack of balance. Of the 18 chapters, no less than 10 deal exclusively with the kidney. In contrast, there are only two chapters on the intestine. Salivary glands, gastric secretion, exocrine pancreas, gall bladder and liver cells have one chapter each. This is clearly not a reasonable balance either in terms of current research interests or with respect to general importance. Furthermore, it means disturbingly uneven presentation with regard to depth of treatment and level of detail. Thus, while Boulpaep (Yale) devotes 47 pages exclusively to a discussion of kidney electrophysiology, Schultz (Houston) uses 31 pages in the only chapter on the small intestine and Schulz and Ullrich (Frankfurt) have 41 pages at their disposal to deal with all aspects of pancreatic membrane transport biology, including the electrophysiology! Nevertheless, Schulz and Ullrich's chapter on the pancreas is a model of clarity and also seems more up to date than many others, betraying the fact that the greater part of these two books must have been finished in late 1976 or early 1977, although some more recent references seem to have been brought in at the proof stage.

The many chapters on kidney transport biology have their problems. In spite of separate chapters on electrochemistry (Khuri, Beirut) and electrophysiology, there is extensive repetition, particularly of the electrophysiology (even of some of the figures!) in chapters on sodium chloride (Windhager, Cornell) and potassium transport (Giebisch, Yale). One figure illustrating Na-glucose co-transport in membrane vesicles (data of Kinne, Frankfurt) is shown three times (pages 156, 426 and 555). The interaction between transport of sodium and organic solutes, originally discovered by Weymouth Reid at the turn of the century, rightly features prominently both in the kidney section, in an excellent review by Ullrich (Frankfurt), and in sections on the intestine and the pancreas.

Immediately following the massive kidney sections is a comprehensive chapter on the salivary glands by Young (Sydney). It is perhaps surprising that salivary glands should be much more extensively treated (more than 100 pages) than the stomach (Forte and Machen, California) or the pancreas, but at least we have here a very complete (up to 1977) account of the transport physiology of these glands. The completeness is, however, somewhat at the expense of clarity. It seems unlikely, for example, that the non-specialist will find the 20 pages dealing with salivary gland electrophysiology (not a single illustration here!) easy going.

One cannot help wondering what readership the editor of this beautifully produced volume had in mind. The 10 very detailed kidney chapters must be attractive to nephrologists who might also enjoy the comparatively short but generally clear accounts of the other transport organs (or some of them; where is, for example, the placenta?). The title is, however, misleading, as it seems to announce a comprehensive treatment of membrane transport in the transport organs. What a pity that this last volume has only become a *Membrane Transport Biology* for nephrologists! □

Autoradiographic techniques

Tim Appleton

Techniques of Autoradiography. Third edition. By A.W. Rogers. Pp.429. (Elsevier/North-Holland: Amsterdam, New York and Oxford, 1979.) $59; Dfl.133.

IT is always a difficult thing to write a book covering a wide range of techniques. Rogers has tackled his task with an infectious enthusiasm and I admire the courage and hard work which has gone into this work. Unlike the earlier editions, this edition is conveniently split into three main parts; the theoretical basis of autoradiography (129 pages); the planning and interpretation of autoradiographic experiments (151 pages); and description of autoradiographic techniques (126 pages). There is also a useful appendix of data which any autoradiographer will appreciate.

I wish I could be enthusiastic about this book. As with earlier editions the descriptions of techniques are mingled in with the text. It would be much more helpful to the beginner and expert alike if detailed descriptions of techniques were set out clearly in the form of a schedule, in heavy type-face, so that they can be easily found and followed. The chapter on photomicrography is not as helpful as it could be, because the quality of the illustrations is very poor — worse than in the first edition. I suspect that this may be the fault of the publisher, as some of the figures which are 'identical' with those in the first edition are clearly at a higher magnification in the third edition, yet the captions still show the lower magnification. Figure 54 in the third edition is of the same field as figure 31 of the first edition; both figures show a magnification of × 135, yet the third edition plates are magnified a further 1.4 times. Such errors are frequent and should have been noticed by the author at the proof stage. Considerable clarity has been lost in many of the illustrations and some of the line drawings are so faint in the review copy that they became irritating. Captions are frequently placed in awkward positions and orientations.

References throughout were fairly complete but did not give titles. Occasionally I found that the reference quoted was not always the authoritative one but taken from a symposium report or review. This resulted in some inaccuracy which might confuse the reader.

The first edition of this book appeared in 1967, was 335 pages long with 77 illustrations. The third, "completely revised", edition has grown to 429 pages with 98 illustrations. I thought that the first edition was too long and my immediate reaction to the latest edition is much the same. However, there is often some benefit in discussing techniques in such a lengthy manner; I found my interests in autoradiography rekindled as I read on. Such length is only really acceptable if the price can be kept at a reasonable level, and I fear that a cost of around £30 will prove too high for the younger scientist.

It is inevitable that a book can never be up to date, and this is certainly true of this one. I would have liked to have seen more discussion of the use of scintillators to increase autoradiographic sensitivity, and on the localisation of diffusable substances at the level of the electron microscope. But then the book would have been even longer and, I fear, more expensive still. □

17 January 1980

A new responsibility for science

A major impact of public reaction to the Soviet invasion of Afghanistan has been to legitimate the slowing down — and in some cases even the reversal — of efforts to limit the global spread of nuclear weapons. The most obvious manifestation of this process has been President Carter's decision to defer consideration by the US Senate of the new Strategic Arms Limitation Treaty (SALT II), concluded last year after lengthy negotiations with the USSR. But the impact of the Soviet moves is already making itself felt across a wide range of non-proliferation initiatives — and the net result can only be to bring the threat of nuclear war a step nearer.

It seems inevitable, for example, that the new strains on East-West relations will provide one more hurdle to the successful negotiation of a comprehensive test ban, severely decreasing hopes for an early agreement. In Pakistan, US moves to cut off military and economic aid last year in an attempt to wean the country away from nuclear weapons production are now being reversed to help provide a counterweight to the Soviet presence in nearby Afghanistan. And to mollify Pakistan's own neighbour, India, State Department officials in Washington are said to be dropping their opposition to the export of highly-enriched nuclear fuels for the Tarapur nuclear plant, despite India's continued refusal to accept international safeguards.

To warn of the dangers inherent in these moves is in no way to condone the Soviet Union's actions, nor to deny that the USSR must share a large part of the blame for their implications. But as far as US policy is concerned, it is important that the realities of the situation are not confused with images of that reality.

The paradox of President Carter's position, for example, is that by taking a firm stand on international issues such as Iran and Afghanistan, he has regained a reputation as a political leader previously lost for failures in relatively unrelated domestic spheres, namely energy and rising inflation. Furthermore the defense industry had not been slow to point out the domestic merits of increased military spending. Pentagon officials, for example, point out that in the past defense-sponsored research has provided a major boost to civilian technologies — and that given current national concerns about declining rates of innovation, increasing the military R&D budget could again help efforts in this direction.

The volatility of US politics tends to create a rhetoric designed primarily for domestic consumption. And in many ways the potential political gains that might have been achieved by supporting SALT have been overtaken by the gains of undercutting the same agreement.

No-one can pretend that the way forward for arms control is clear. But one strategy that could be pursued with vigour would be to separate discussions aimed at limiting nuclear weapons as far as possible from the temporarily sinking ship of *détente*. In the past, the scientific community has ably taken on this role, using its position on the fringes of the political establishment to keep open lines of communication that might otherwise be lost. Last week the council of the American Association for the Advancement of Science passed a resolution emphasising the continued need to support arms control efforts, and drawing attention to the particular responsibility of scientists to help this process (see page 234). We support the AAAS's efforts, and urge British scientists to do likewise. □

No engineers without teachers

AT last the Finniston report on the training and status of engineers in Britain has been officially published. The history of leaks of the report has been so long that it is rather an anticlimax to have the real thing on one's desk*; *Nature* described the bulk of its recommendations last summer (2 August 1979, page 352). We support most of them as indicating a practical, as opposed to big-headedly political route towards the improvement of Britain's economic competitiveness. Britain has too long neglected and rejected the applied scientist and engineer as a creator of wealth; the paradigm of economic activity has been the City, where paper rather than materials are moved: a second-order economic activity. There is a strong element of class-consciousness in this anti-technical valuation, and it pervades the whole of the establishment, including the Civil Service. Even the Department of Industry is neglectful of technological change.

Perhaps Finniston can blow a wind of change through all this — but it is unlikely. A sense of depression is increased if one looks at the figures for the numbers of science teachers in training in England and Wales — for these are the people who will influence the outlook of the next generation. Take physics and chemistry, for example. Of 19,500 physics teachers in secondary schools in January 1977, only 43% were actually qualified to teach physics. Of 18,800 chemistry teachers, half were qualified. The majority of teachers were 'filling-in', when their basic training was in another subject. In January 1979, the annual number of new physics teachers needed to fill vacancies and begin to replace unqualified teachers was estimated by the Department of Education and Science to be 1,300. In chemistry the number was 600.

Against this, in 1979 just 244 physics and 345 chemistry graduates entered one-year DipEd courses to learn to teach — satisfying roughly one fifth of the need for physicists and one half that for chemists.

Mathematics is worse and biology better off than this. Of 48,300 maths teachers (maths is a compulsory subject), 62% are qualified, and there is an annual need (DES figures) of 4,300. The input of graduate trainees in 1979 was 636 — one seventh the need. In biology there are 20,900 teachers of whom 55% are qualified; the annual need is 600; and the 1979 graduate input was 657, satisfying demand.

In all subjects the position is worsening. Three years previously there were 412 graduate physics entrants into teacher training (244 in 1979); 438 chemists (345 in 1979) and 800 mathematicians (636 in 1979). (Biology fell slightly from 691 in 1976 to 657 in 1979.)

Without well-qualified science teachers, there is little hope for the future of science and engineering in Britain. Now is also time to discuss how to attract good science teachers. □

United States

David Dickson reports from the annual conference of the American Association for the Advancement of Science in San Francisco

Council supports arms control

FOLLOWING a public meeting at which a number of scientists described the increasingly urgent need to limit the proliferation of nuclear weapons, the council of the American Association for the Advancement of Science agreed last week to establish a working group "to help organise and mobilise resources towards nuclear arms control."

The AAAS council also agreed that efforts for directing science towards peace rather than war should be a major theme of next year's annual meeting, which will take place in Toronto.

Both decisions formed part of a resolution on nuclear weapons control submitted by seventeen members of the association, which pointed out that "improving the effectiveness of science in the promotion of human welfare is an objective and a special responsibility of the AAAS."

By adopting the resolution, the AAAS council agreed to support both US efforts to obtain effective bilateral nuclear arms limitations and the completion of the Comprehensive Test Ban Treaty. It also expressed opposition to "the development by any country of new weapons systems which make verification more difficult, or pose a first-strike threat."

Supporters of the resolution point out that the latter is an implicit reference to, among other things, the recent decision by President Carter to recommend the deployment of a new generation of Minuteman missile, the MX.

The council also agreed to support the development of plans for the step-by-step conversion by all nuclear-weapons-producing nations of facilities for nuclear weapons production, research and testing, into science and technology facilities for peaceful uses. Such "conversion" plans are expected to be made the subject of a special session at next year's meeting of the association. □

Gene resource programme called for

In a further resolution, the AAAS council gave its support to efforts to develop a national gene resource conservation programme. A resolution was passed which argued that there is insufficient support in the US for addressing the rapid depletion of germplasm resources of natural ecosystems, and that there is currently no comprehensive or effective national programme which would ensure that important germplasm resources are safeguarded.

Military support of basic research defended

RECENT increases in military support for basic research are rekindling the fierce debate over its social and ethical implications dormant for much of the past decade following widespread criticism during the Vietnam war era.

Supporters of military funding for science, addressing a session of the AAAS meeting, not only emphasised its importance for the long-term development of new weapons systems, but also claimed that through technological spin-offs — which have ranged from synthetic rubber to large-scale integrated circuits — military-supported research can help stimulate general industrial innovation in the US.

Critics, however, argued that the military control of research meant such research would inevitably be skewed towards the production of weapons of mass destruction, and was therefore in fundamental conflict with the well-being of mankind.

Dr George Gamota, director for research in the office of the Under-Secretary of Defense for Research and Engineering, told the audience that the department was trying hard to repair the working relationship with the scientific and engineering communities that had been weakened in the mid-1960s and early 1970s.

Particular emphasis was being paid to restoring defense support for university research. Forty per cent of the basic research currently funded by DoD was carried out by universities; and over the past three years, university support increased by nearly 70%, although overall support for basic research increased by only 30%.

The need for military support for basic science, said Dr Gamota, "is rendered even more urgent by the relative decline in the extent of basic research conducted internally by industry or supported by the industrial sector on the academic community."

Referring to the Mansfield Amendment, passed in 1971 and restricting DoD support to research with a potential relationship to military needs, Dr Gamota said there was nothing in the act which touched upon the department's ability to support basic research. "Only the availability of funding and the level of interest of other agencies determines how wide a spectrum of research support is possible in the context of the DoD mission," he said.

Dr Gamota argued that it was impossible to single out any major basic research effort, particulary a new field, that could be categorically ruled out as potentially irrelevant to the Defense Department. "Our job is to follow the national trend and ensure that adequate funding is provided in areas of potential interest to DoD, and primarily only funding limitations and the extent of other agency interests limit our scope". The aim and goal of the department's support of basic research was "to ensure that the support will keep us technologically ahead of the world."

A full-blooded attack on such thinking, however, came from Professor George Wald, emeritus professor of biology at Harvard University, who accused military planners of helping create a "mad nightmare of a world in which we are putting our children."

In contrast to those who argued that the US was now lagging behind the USSR in military technology, Professor Wald said that America was still five years ahead, both qualititatively and quantiatatively. And although he admitted that he had no confidence in the peaceful intentions of the Soviet Union, it was the US, he said, which was currently leading the arms race.

Earlier in the conference, Professor Philip Morrison of the Massachusetts Institute of Technology, argued that through a mixture of judiciously chosen policies it should be possible to cut the military budget by 40% to 50% while preserving the same level of national security as exists at present.

"The key point is to buy what we need, and organise to use it as we need. We need not buy systems because one or another service or firm wants us to do so, or because once in another world they were useful, or because the Soviet or someone else has them," Professor Morrison said.

Recent events at the global and domestic level made it important that scientists in the AAAS and elsewhere take a close look at science in the service of war. "The US has largely paced the arms race," he said. "We can cut military research and development to a reasonable size, and restore the talent and resources thus set free to the growing needs of civil society." □

0028-0836/80/03234-01$01.00

Nuclear accident casts a long shadow

EVIDENCE that last March's accident at the Three Mile Island nuclear power plant has already cast a long shadow over public attitudes towards a broad range of activities assosicated with nuclear power was presented by various speakers to last week's meeting of the American Association for the Advancement of Science.

Speaking at a session on risk in technological society, Dr Peterson, until recently director of the US Congress' Office of Technology Assessment and a member of the public commission established by President Carter to report on the accident, said that in the climate following the accident, public reaction to any incident involving a major release of radioactivity into the environment would almost certainly lead to demands for an end to the use of nuclear energy. "If in the interim we have tied our way of life to electricity from nuclear, the economic and social costs will be major indeed," he warned.

Dr Peterson drew attention to recent recommendations that plans for evacuating the residents close to a nuclear plant be developed before a plant is authorised to operate. Several nuclear physicists with the Nuclear Regulatory Commission, for example, had recently said that in the event of a future nuclear plant accident — and given the same amount of information as was available at the TMI incident — they would again recommend evacuation.

"Together these facts demonstrate that when individuals have the opportunity to dig deeply into the operation of nuclear power plants, they conclude that it is only a matter of time before an accident releasing a devastating amount of radioactive material occurs. Why else would we need evacuation plans?" he asked.

Dr Peterson suggested that although the potential for a catastrophic accident raised the most amount of public concern, a more serious risk in the long run could come from the cumulative impact of countless minor releases of radioactivity. These ranged from uranium mill tailings, through the disposal of radioactive wastes, to the use of part-time employees as "sponges" to carry out brief tasks in highly contaminated areas to save regular employees from excessive exposure.

Another lesson discovered recently, he said, was that the nuclear industry had not learnt its lesson. He quoted, for example, advertisements that had been placed in major newspapers by the Edison Electric Institute, claming that the electric companies agreed with the Kemeny Commission's message that nuclear power could proceed, but with caution.

"The Kemeny Commission said no such thing," protested Dr Peterson. "The introduction to our report carefully explains that our assignment limited us to matters bearing directly on the Three Mile Island accident, and that we made no judgements on a number of other issues — for example, the disposal of radioactive wastes — that must be considered in deciding whether nuclear power is basically safe."

A different slant on the impact of increased public concern about nuclear hazards was given by Nobel prizewinner Dr Rosalyn Yalow in the course of a public lecture on radioimmunoassay.

Dr Yalow referred in particular to the recent press coverage that accompanied the decision by various states temporarily to close radioactive waste disposal sites. She suggested that the so-called problem of radioactive waste disposal from hospitals and medical centres was really not a problem but rather a figment of the "small minds and fertile imaginations" of various regulatory agencies.

"An unreasonable fear of any level of radiation associated with radioactivity or nuclear energy generated by newspaper headlines and publicity seekers was now pervasive throughout our society," Dr Yalow said. "Because of this we dissipate research talent and funding on make-work projects in response to unreasonable fears in make-work situations."

She cited, for example, the recent announcement that a number of research groups are to study possible long-range health effects secondary to the reactor accident at Three Mile Island. The maximum estimated dose received by anyone living near the reactor during the accident was bout 70 millirems, less than one third the amount they would have received by spending a year in Colorado.

"If these were the maximal doses received one can predict with absolute certainty that, other than psychological effects, no physical aberration would be demonstrable. Yet we waste time, money and research talent — and generate more psychological stress than would otherwise occur in unnecessary make-work of no scientific merit." □

Women scientists still lose out to men

DESPITE almost a decade of affirmative action and raised consciousness, women continue to face a number of barriers in pursuing a scientific career, according to Mrs Betty Vetter, executive director of the Scientific Manpower Commission.

Speaking at a session on employment opportunities for science and engineering doctorates, Mrs Vetter said that women had approximately doubled their share of doctorates in science and engineering since 1970. But they still tended to be employed in lower-paid jobs than men, to have more difficulty in gaining tenure at universities, and to suffer a much higher rate of unemployment.

"It is not at all uncommon to find persons who believe that affirmative action programmes for women or for minorities have given women an edge in employment opportunities, but the statistics do not seem to bear out an assumption of equal treatment, even at the entry level," she said.

For example, while it might be expected that women who obtained their PhDs in the 1950s and 1960s had not advanced as rapidly as men from the same cohorts, one might expect to find that those from more recent classes would be advancing at rates comparable to men: yet evidence produced by a survey carried out last year by the National Academy of Sciences showed that this was not true.

In the life sciences, for example, 23% of academically-employed men earning PhDs in the period 1970-74 had been appointed assistant professor by 1977, but only 11% of women in academic careers earning PhDs in the same period. In contrast, 27.5% of the women PhDs held the rank of lecturer or instructor, compared to 15.5% of the men.

In the federal government, a number of studies had shown that women still tend to advance in their careers more slowly than men, overall lagging by an average of 1½ to 2 civil service grades. For example, in 1978 women made up almost 31% of all microbiologists employed by the federal government, but their median grade — and their salary average — was about 20% less than that of their male counterparts.

The best possibility for reducing inequity of opportunity for young women research workers appeared to be in industry. In 1977, for example, only 10.8% of all women doctoral scientists and engineers were employed by industry.

Evidence that the general employment prospects for young research scientists and engineers is likely to remain gloomy through most of the 1980s was presented by Mr Alan Fechter, head of scientific and technical personnel studies for the National Science Foundation.

This situation was created by a number of factors, such as the increased hiring of research workers into non-tenure-track positions, a general reduction of promotion opportunities, declining salaries relative to other sectors, and cutbacks in 2-year and marginal 4-year institutions as a result of falling student enrolments. □

0028-0836/80/03235-01$01.00

Study shows only 1% real growth in basic research spending

THE combined effects of increasing inflation and Congressional budget-paring have meant that a strong push by the Carter administration for continued real growth in funding for basic research was successful "to only a limited degree" over the past year, according to a survey of actions taken on the 1980 budget prepared by the AAAS secretariat and published last week.

The survey points out that, as in previous years, Congress substantially increased the basic research budget of the National Institutes of Health but pared back the increases proposed for most other agencies.

"Excluding NIH, the total income increase in basic research over the fiscal year 1979 comes out at about 11%, compared to 13% proposed in the budget. With inflation approaching 10%, compared to less than 7% anticipated in the budget, not much real growth is left."

The survey points out that although the administration failed to convince Congress to hold R & D funding for the NIH to the level appropriated for 1979, the rate of increase was substantially slowed from that enjoyed by NIH in recent years.

In contrast, although Congress had initially moved to reduce the proposed levels of expenditure for military research and development, as attention focused on SALT II and on Iran, legislators changed course and approved virtually the full amount recommended by the President.

"In general, Congress seems to be fully committed to providing full support to a large and expanding military R & D programme" says the survey. It points out that no major defence policy issues were fought out between Congress and the administration in the discussion of the military R & D budget.

The net effect of congressional actions, it concludes, was to raise support for basic research by one per cent. □

Carter plans 13% research boost

PRESIDENT Carter is to ask Congress for an increase of about 13% in financial support for basic science in the fiscal year 1981 — just enough to keep slightly ahead of expected inflation and to allow for real growth.

In his budget request, due to be presented to Congress on 28 January, the President is also expected to place particular emphasis on funding for engineering and the physical sciences, which have recently received less attention than the biomedical sciences.

The President gave a preview of his budget request on Monday at the presentation of 20 national medals of science, the highest honour awarded to US scientists and engineers by the federal government. He said that the net effect of his request will be to increase support for basic science by 40% during the first three years of his administration — officials said later that the increase for the first two years was 24%.

The budget for the National Aeronautics and Space Adminstration is expected to reflect the impact of the additional costs of the space shuttle on space programmes. In particular, NASA officials have been unable to reverse an earlier decision by the Office of Management and Budget not to support research on an ion drive system which is essential if a joint mission is to be mounted to the comet Tempel 2 with a 'fly-by' of Halley's comet in 1985.

However, this year at least two projects are expected to be approved: the gamma ray observatory, and a national oceanographic satellite.

Locust research cut

RESEARCH on locusts at the UK Centre for Overseas Pest Research is one of the casualties of recent cuts in government spending. For the past 50 years, the centre has combined research and field control and has been a major centre for visiting scientists from developing countries to do research and for the training young scientists.

With the cuts, all field work, research and training will stop and the locust experts employed by COPR will be available only as consultants. Within six to eight years, according to Dr Haskell, director of the centre, most of them will have left. The United Nation's Food and Agriculture Organisation in Rome has taken over the monitoring of potential areas of plague evolution and of organising international control measures but Dr Haskell fears that much of the centre's basic research on locusts will not be taken up elsewhere.

The centre's first director was Sir Boris Uvarov who determined that what had been thought of as two distinct species of locust were different forms of one species: the less innocuous 'grasshopper' and the plague-causing destroyer of crops. More recently, the centre has been renowned for its work on the relation of swarming to meteorological conditions and in establishing the importance of pheromones to swarm evolution.

BIONIC BRITANNIA
WE USED TO HAVE THE TECHNOLOGY

Time running out for technology

FAR from making a smooth transition into the post-industrial world, Britain is heading for much greater competition, says a government report* published last week.

Britain must be prepared particularly for developments in "information technology and biotechnology, and of industries of high growth potential arising from the increasing need to conserve energy and materials" it says.

The booklet is the result of a working party, headed by Sir James Menter, of the UK's Advisory Council for Research and Development. ACARD called for the report principally to project the impact of potential technological change on employment, but the authors found it impossible to reach quantitative conclusions. But they argue "more unemployment results from loss of market share following a failure to innovate than from the introduction of new technology. Conversely, if new technology leads to an increase in market share there is generally an increase in employment opportunities".

The least predictable recommendations in the report are that the UK should consider setting up an agency to facilitate the import of new technologies from countries which have already taken a lead; and that large companies with R & D results that they do not intend to use should be encouraged to set up or seek out small firms better able to utilise such results.

The report suggests that "attempts by firms or industries in the UK to avoid competition from technologically more adept foreign competitors by specialising in certain (usually high-priced) sectors of the market (for example the motor cycle industry), by continuing to accept lower real wage rates and higher manning levels (car industry) are ultimately doomed to fail."

Robert Walgate

Health monitoring endangered at Séveso

THE lack of facilities available to local scientists for monitoring the health of people exposed to 2,3,7,8-tetrachlorodibenzo-p-dioxin (dioxin) at the Italian town of Séveso in July 1976 is endangering the health surveillance programme.

This is just one of the conclusions reported in the minutes of the International Steering Committee (ISC) of the Lombardy region's special office for Séveso. The ISC — composed in the main of internationally renowned scientists — was formed in the wake of the Séveso accident to consider the implications of exposure to dioxin by the local population.

To save the health surveillance programme, the ISC says it is of crucial importance for either local or national government to make a commitment to establish more permanent staffing within an epidemiological group set up specifically for the "Séveso follow-up". And in order to overcome the disillusion of local doctors in the current surveillance exercise, the ISC consider that one of the first priorities of the epidemiological group must be to enhance the motivation and to increase the involvement of local medical practitioners and hospital staff in a long-term programme.

It is the view of the ISC that the skin disease chloracne is one of the best indications of exposure to dioxin. Individuals with chloracne, it says, represent a group "for whom biologically significant (as distinct from presumed) exposure [to dioxin] can be reasonably accepted". The ISC believes that it is this group which faces the greatest health risk and which should be monitored for many years, perhaps even for life. To assess the risks for this sector (a group composed entirely of children) it is suggested that two matching control groups — one not exposed to dioxin, and the other possibly exposed — should also be monitored.

Dioxin is known to be both a teratogen and a carcinogen in animals. Data on the danger it poses to the human fetus are simply not available. However, the ISC acknowledges that there may still be long-term risks to the fetus of "chronic exposure to very small amounts" of dioxin and the committee recommends that a registry be kept of severe and minor congenital malformations; birth weight; prenatal and postnatal mortality rates; and the rate of spontaneous abortions.

An efficient cancer registry based on morbidity as well as mortality is also urgently required says the committee. Maintenance of such a registry is both difficult and time consuming, but the ISC points out that many countries carry out such programmes.

Over 1,000 individuals employed in the chemical industry are known to have been exposed to significant levels of dioxin over the last 30 years and the committee is anxious to obtain any information about their health problems. The ISC says that this information will help the Italian authorities to assess the adequacy of the health programmes for the Séveso area.

Failure to implement these proposals will mean that much information, important to the well being of the Séveso population, will be lost. If the ISC recommendations are ignored, many of the scientists on it could withdraw.

Eastern Europe

Scientific exchanges are needed for détente

SCIENTIFIC exchanges "agreed by treaty"should continue, irrespective of developments in Afghanistan, according to East German radio last week.

East Germany has a special interest in preserving *détente* at this stage — the first ever formal summit between Party Leader Erich Honecker and the West German Chancellor Helmut Schmidt is expected this spring. However, political spokespersons and commentators throughout the socialist bloc seem to be making a concerted effort to minimise the effect of the Soviet intervention in Afghanistan on *détente* in Europe.

Eastern hopes in this regard have undoubtedly been bolstered by the slow response of Western European governments in support of Carter's measures. The UK, for example, will hold a Cabinet Office meeting later this week to discuss British action (if any). An environmental working party is currently in Moscow, discussing odour prevention, under the auspices of the Intergovernmental Joint Commission for Trade and Technology. According to a representative of the Department of Trade, the meeting was probably allowed to continue because no member of the British delegation was of sufficiently high rank to warrant its cancellation at this stage.

Accordingly, while denying that the Soviet Union has, in fact, done anything untoward in sending forces into Afghanistan, the socialist bloc commentators continue to urge *détente.* "Economic, scientific, technical and cultural links between countries", said Viktor Glazunev, one of Moscow Radio's chief "news analysts", "make up what you might call the material fabric of *détente.* A blow at the fabric strikes a blow at *détente* itself . . ."

The need to bolster *détente* is all the more urgent, with the Hamburg Scientific Forum only a month away. This forum is intended to be a meeting point for individual scientists to discuss problems in the context of East-West scientific cooperation, including contacts, communication and the exchange of information. Clearly world events, and the general issues of academic freedom and human rights are bound to be raised in that context.

Indeed, one human rights lobby, led by Valentin Turchin, and John Macdonald Q.C., would have suggested that western delegates should press for the forum to be postponed, until such time as the dissident physicist, Yurii Orlov, is released from strict regime labour camp. (The rationale of their argument being that Orlov, convicted in 1978 of slandering the Soviet state, had, in fact, been collecting material on alleged Soviet breaches of the Helsinki accords, in his role as founder member of the clandestine Helsinki Monitoring Group in Moscow.)

Other action groups, while agreeing that the forum should take place, see it as a valuable platform for human rights. "In our opinion", says the Scientific and Medical Committee for Soviet Jewry, "for the exercise to be meaningful, not only should the Hamburg meeting include on its agenda the question of the freedom of the movement of scientists; also any scientific body must ensure that a clause dealing with this problem is written into its constitution."

This too is essentially the attitude taken by Bruce Kiernan, human rights coordinator of the American Association for the Advancement of Science, which, together with the Committee of Concerned Scientists will be holding a human rights' briefing for the US delegates to Hamburg early in February.

Those French scientists that are concerned with human rights have not yet made a formal statement; it is understood, however, that they will press for the guaranteeing of the personal security of scientists as an indispensible preliminary to any international cooperation — and that, the Helsinki accords being indivisible, it is impossible to dissociate "exchange programmes" from human rights.

NEWS IN BRIEF

China issues new titles for engineers

CHINA'S State Council has issued temporary provisions for titles for the country's 21.5 million engineers and technicians. Issued on 28 December, the council's recommendations call for the titles, senior engineer, engineer, assistant engineer, senior technician, and experienced worker or technician to be granted according to previous contributions, vocational proficiency, previous schooling and seniority. The senior technician or experienced worker designations will be granted to those who have special skills, can solve key technical problems and have distinguished themselves in work. An editorial in the *Beijing Workers Daily* says the provisions "will help overcome the egalitarianist tendency that calls those who work more and better and those who work less and worse the same". Assessment will be done by special groups consisting mainly of experts. Party committees should guide the groups instead of interfering with their remit, the editorial says.

French unions refuse reactor safety report

FRENCH trade unions representing nuclear reactor workers have refused to accept the conclusions drawn in a safety report issued by the French electricity board. Released to the unions last week by the Director of Equipment, the 43 page report concludes that the cracks found in the tubular heat exchanger plates in the reactors, Tricastin I, Gravelines I and Dampierre I "do not constitute a risk to the workers or the population" and that "all the faults will be able to be monitored during the reactor's operation." The Communist trade union, the CGT, has demanded increased safeguards in the functioning of the safety valves in the primary cooling circuit. The socialist trade union, the CFDT, has objected to "numerous uncertainties in the security and safety of the installations" and the unaligned Force Ouvriere protested a lack of completeness in the report. "The politics of nuclear information is a reality and we cannot tolerate witholding information of any sort".

French Academy elects first woman to full membership

THE French Academy of Sciences has, for the first time in its 300 year history, elected a woman as a full member. She is Mme Yvonne Choquet-Bruhat, a leading figure in the field of general relativity for 30 years, who has pioneered work on the Cauchy problem and the mathematical structure of Einstein's equations. The Academy, which admitted Pierre Curie and closed its doors to Marie Curie, has thus finally, if belatedly, recognised the contributions of women to knowledge. Speaking at the time of her election Mme Choquet-Bruhat said that she hoped she would not be the sole woman member of the Academy for long. Now that the breach has finally been made, it is expected that many more of France's talented women scientists will follow.

Jim Ritter

British nuclear reactors closed for cracks

TWO Magnox gas cooled reacors at Dungeness near Dover, have been closed for an indefinite period because of cracks in the expansion bellows of their primary cooling circuits. The cracks, up to a meter long, are located in the welds of the expansion units inserted into the 4 ft diameter cooling pipes. Originally discovered during the biennial routine inspection of reactor 1 in August 1978, the cracks were ruled to have been present during manufacture and not to have grown during the lifetime of the reactor. But a more detailed ultrasonic search on reactor 2 during its biennial inspection in April 1979, showed meter long cracks in many of the 24 bellows mountings. Reactor 2 is still shut down. The Central Electricity Generating Board, in conjunction with the Nuclear Installations Inspectorate then decided to close down reactor 1 for further tests last weekend. The CEGB will prepare a detailed safety report on the situation which must be passed by the NII before either reactor is restarted. According to the *Guardian*, engineers are reported as saying that the 16 year old reactors are unlikely to ever be used again.

British groups organise against transport of nuclear waste

THE London Regional Anti-Nuclear Alliance has announced a campaign to prevent the weekly shipment of three tons of nuclear waste from Dungeness to the Windscale reprocessing plant from passing through London. Citing US legislation which bans nuclear waste transport through New York City as a precedent, the Alliance says that the three previous derailments of trains carrying radioactive waste means that "it is only a matter of time before a serious accident occurs". According to the Alliance an accident damaging the flasks could cause contamination within a 12 mile radius producing 8000 additional cancers and would render the area within a 3 mile radius uninhabitable for 70 years. The Alliance says that the flasks have not been tested to withstand impacts in excess of 30 miles per hour or fires lasting longer than 30 minutes and it calls for a rerouting of trains around London and other densely populated areas as well as the release of the government's evacuation plans in case of an accident.

Piperno still held without evidence

THE case of Italian physicist Franco Piperno, extradited to Italy from Paris last summer for "actions against the State" has entered a new phase. After 22 months of hearings and 20,000 pages of documents on the assassination of Aldo Moro, seven magistrates have recently published a 186 page report in Rome. The magistrates could find no evidence linking Piperno and his two colleagues in the Workers Autonomy Movement, Antonio Negri and Lanfranco Pace, with the assasination and have called for an additional inquiry. The report says that it "is extremely difficult to furnish proof, and because of the complexity of the accusation against them, the case of the three Autonomy leaders ought to be separated from that of the Red Brigades and a supplementary inquiry be effectuated". According to *Le Monde*, the prosecution believes it may find the evidence it needs from the recent testimony of an informer, Carlo Fioroni.

Bangladesh LANDSAT programme enters second phase

A THREE day international workshop on disaster preparation and remote sensing inaugurated the installation of an advanced ground station in Bangladesh for receiving satellite data on flood indications and major meteorological disturbances. Automatic data collection platforms will also be set up along the major rivers in Bangladesh to assist in water management and planning. Chaired by Dr B.M. Padya, Chief Technical Advisor of the World Meteorological Organisation, the conference was attended by representatives from Bangladesh, India and Thailand.

Satellite data has already been used in Bangladesh for land accretion and land use studies, changes in water reservoir levels and siltation surveys. Remote sensing has revealed desertification in northern districts and LANDSAT information has been used for afforestation projects, crop distribution studies, estimation of crop yields and salinity intrusion studies.

Shaded countries are members of the League of Arab States. Somalia, not on the map, is also a member

Planning science in the Arab world

Many problems faced by scientists in the Arab world are common to all Third World countries. **Dr A B Zahlan** takes the Arab case to test some general assumptions about the problems of science and technology in developing countries

SCIENTIFIC research in the Arab world has been growing at a steady pace during the past three decades. Two thirds of this activity has been in the agricultural and medical fields where extensive institutions and qualified manpower now exist. The research work is generally of an applied nature and dwells on current problems. By contrast, research activity in all other fields is on a limited scale. In the basic sciences,for example, it does not account for more than 5% of publication output, and in areas of a vital developmental, industrial and defence nature — such as metallurgy, civil engineering, hydrocarbon chemistry, electronics, aerospace, — it is on a vary small scale.

The fields of scientific research that are normally undertaken by university professors have been severely affected by the generally poor working conditions in the fifty or more Arab universities. Teaching loads are high, job security is low, libraries are poor or non-existent, laboratory and work-shop facilities are restrictive, administrative red tape is excessive, intellectual stimulation is limited, standards for academic promotion are wanting, and technical and secretarial support staff remain scarce. These conditions of course do not prevail at the same level in all institutions, and an active research programme often flourishes in difficult circumstances thanks to the energies of a few researchers. Moreover, a small number of scientists have created permanent links with research groups in Europe or the US.

Various statistical compilations set a figure of about 40,000 for the number of researchers in Arab countries. These staff more than 500 R&D institutions and 50 universities, the latter enrolling more than 1 million students. However, the constraints on their capabilities have reduced their contributions to the scientific literature to a meagre 1,500 per annum. The absence of adequate publications in the applied sciences at one stroke limits the development of appropriate teaching materials and condemns workers to researching and rediscovering similar problems. The present level of funding in the range of $1-2 per capita per year during the 1970s has, of course, also been a constraining factor.

Despite these drawbacks, the scientific communities in the Arab world have accumulated considerable experience and have experimented with a broad range of ideas and instruments. Many of the problems faced by Arab researchers are common to Third World countries, and the Arab experience thus has a universal value.

The concepts underlying much of current thinking in science and technology in developing countries emphasise the need for high level manpower, the integration of research activities in science and technology with development plans, the central planning and management of the activity, the linking of the central management, (often called 'science policy making body', SPMB) to the highest decision maker, and so on. These notions are so reasonable that very little in the way of empirical testing has been attempted. The Arab experience in the use and application of these notions has made it possible to evaluate these concepts in real-life situations.

One finds, for example, that science policy making bodies still subscribe to the belief that the shortage of scientific manpower is an obstacle to the development of research programmes. However, the expansion of the secondary and university educational systems in the Arab world as well as the access to foreign educational systems (the USSR, eastern and western countries, and North America) have combined to eliminate the supply of high level manpower as the determining factor in scientific research or in any other function where such manpower is needed. Thus, although the Lebanese National Council for Scientific Research (NCSR) subscribed to the principle that the formation of scientific manpower was a necessary step prior to the funding of research projects, only 10% of its own grants went to recipients of NCSR

Dr Zahlan is currently researching the history of technical change in the Arab world. He was professor of physics at the American University in Beirut and is a member of the UN Advisory Committee on Science and Technology. His book Science and Science Policy in the Arab World is published by Croom Helm this week.

0028-0836/80/03239-03$01.00

advanced study fellowships; and the recipients of the remaining 90% of the grants had not required NCSR support for their higher education, having completed their advanced education before the NCSR adopted its manpower formation policy.

The feasibility of centrally planned scientific activity has been taken for granted by developing countries, and especially by UNESCO's Science Policy Division. Egypt has been committed to such an approach. More than eight major changes in its SPMB's during the past two decades clearly undermines the effectiveness of central planning. The Science Council (established in 1956) created a system of committees for the planning and management of scientific activity. Between 1958 and 1960, it mobilised 3,000 Egyptian scientists to prepare a five-year plan. This effort was sidetracked, however, in 1961 by the establishment of the Ministry of Scientific Research. There were further changes in 1964, 1965, 1968, 1971, 1975 and finally in 1976.

Since 1956 the councils and committees established to plan and manage scientific activity have grown in size and number. By 1977 the Academy of Scientific Research and Technology had 17 research councils and 97 subject committees involving more than 1,300 members for planning and managing its programmes. Of the 97 subject committees only a third held one or more meetings attended by 50% or more of their committee members; and 53% held no meetings. A detailed analysis revealed that there was no correlation between the number of meetings held and the amount of funds appropriated, or between the declared priorities of the Academy's science policy and the activities of the committees or councils or the funds appropriated. Although a basic objective of the Academy is to concentrate on the solution of urgent problems, only 5.6% of 1977 appropriations were committed to projects whose duration was two years or less, and 51% were granted to projects whose duration was five to ten years.

The linkage of the SPMB to the decision-makers has posed a number of interesting problems. UNESCO, for example, advocates that this linkage be to the highest decision maker in the country in order that financial support be guaranteed and that the integration between development planning and science and technology be efficiently effected. Despite the importance given to this linkage in the international literature on the subject, one finds surprisingly little concern for the actual behaviour of these Third World institutions. Since SPMB's are central to the relationship between the scientific community and the decision maker, their stability is vital to the development of effective personal and institutional relationships. The eight major changes in the SPMB in Egypt noted earlier reduce the credibility of such an assumption; such a high level of discontinuity in the institutional framework undermines both the linkage to the decision maker and the human and social relationships within the community itself. In addition to institutional instabilities one must also consider the frequent changes of the officials responsible for the SPMB.

The situation on the decision-maker's side is no less incoherent. Frequent changes in ministers and in policies also occur. Civil disturbances and economic crises take their toll of scientific activity. The first year of the Lebanese civil war, for example, reduced the output of the scientific community there by more than 42%.

Much of the international discourse on science and technology in the contexts of UNCSAT and the UN conference on science and technology for development revolved around the notion of "applying" science and technology to the development process. Yet the major obstacles to achieving such a useful objective were left out of most of the deliberations. These obstacles are due to the structure of the planning process, the inadequate communications between the scientific community and planners, bureaucratic resistance to data collection and dissemination, and the domination of the central planning process by economic, political and financial considerations. The widespread utilisation of the turnkey type of contracts with foreign firms reduces opportunities for applying indigenous science and technology considerably. The character of government operations is important, rather than the institutional link of the SPMB to central authority. As a matter of fact, it does not seem to matter whether the linkage is to the head of state or to the minister of higher education and scientific research.

Most of the Arab countries have now reached a phase where the major obstacles to further progress lie in the weaknesses of the existing institutions, the planning practices of ministries, the means available to university professors to undertake scientific research, and cultural policies.

The international connection

The scientific communities and institutions of the Arab world have evolved a complex set of relationships with foreign countries. To begin with, most scientific manpower engaged in research have relationships with scientists in Europe, the USSR or US. A number of scientific unions already exist in the Arab states and many of these are members of the International Council of Scientific Unions (ICSU). Egyptian scientific councils belong to most of the ICSU councils, and research councils in roughly half the Arab states are members in one or more of the ICSU councils.

Numerous research institutions in the Arab world have been established through bilateral agreements. The nuclear research centres in Baghdad and Cairo, and the bilharziasis research institute in Cairo were established by the USSR and Federal Republic of Germany respectively. In 1942, the US Navy established in Cairo the US Naval Medical Research Unit Number Three (NAMRU-3) which by 1977 had grown to 26 military personnel and 206 civilians (203 from Egypt). NAMRU-3 has played an active role in medical research in Egypt. In 1976, the US and Saudi Arabia signed an agreement through which the US is to assist Saudi Arabia to establish the Saudi Arabian National Centre for Science and Technology (SANCST). The US and Saudi Arabia also have a joint five year $100 million research programme in solar energy.

UN agencies have been involved in a number of different ways in the application of science and technology in developing countries. UN support to scientific research activity, or to the strengthening of indigenous technological capabilities of Third World countries, consumes no more than 1.5% of the $3 billion UN budget. The Arab world share of these $45 million is of the order of $1-2 million.

The number of scientific and technical meetings in the Arab world has been steadily increasing. The Cultural Department of the League of Arab States sponsored these meetings in the fifties. Since then the Arab League Educational Cultural and Scientific Organisation (ALECSO) has been instrumental in convening them. The growing number of scientific associations and societies have also been actively organising scientific meetings.

Likely trends

On the national and regional level, a large number of small scale but steady changes have been registered. New institutions and new universities are created annually. The position that Egypt (with 25% of the population of the Arab world) held in 1950 with virtually the only Arab centre for scientific work (more than 80% of Arab publications in 1950 were by Egyptians) has been changing steadily. In 1967 Egypt produced 63%, and in 1976 55%, of Arab publications; by the year 2000 Egypt's share will be below 40%. This reduction is not due to a decrease of activity in Egypt but rather to an expansion in the other Arab states. For example, the combined output of Kuwait, Libya and Iraq (11% of Arab world population) which was 8% in 1967 increased to 14% in 1976. It is likely that the share of these three countries would have increased to 30% in the year 2000.

The internal movement of scientific manpower between Arab states has been steadily increasing. This has made the development of social and educational services in Arab oil producing countries at a high rate possible. During the past decade most of the increases in the allocations for R&D in the Arab world have taken place in oil producing countries; elsewhere, little increase in funding is recorded.

The Arab scientific communities, the educational systems, their immediate environments, their relationships to the users of technology, and the resources of the Arab states have all been undergoing far-reaching changes. It is very difficult at this moment to identify clearly the new directions that are emerging. On the surface, it would seem that the traditions of the past three decades are firmly entrenched. This can be seen from the CASTARAB 1976 meeting in Rabat, the 1978 Kuwait Fund for Arab Economic Development feasibility study on the proposed Arab Fund for Scientific and Technological Development, as well as the national papers submitted to UNCSTD. Nevertheless a large number of indicators point to the possibility of major departures. Since the early fifties, the production of scientific and technical manpower has been expanding at an exponential rate, with a doubling time of about 5.3 years. If this rate continues, the one million university graduates of 1978 would have grown to more than 12 million by the year 2000. The 24,000 foreign trained doctorate holders could reach a level of 150,000–250,000 by the year 2000.

Meanwhile, the capacity of the US and Europe to drain unwanted high level manpower has been reduced by the economic recession registered there. Furthermore, the size of Arab technical manpower is rapidly reaching a level that makes likely drains an insignificant portion of the total pool of educated manpower. The absorption of this enormous manpower cannot be achieved without effecting major structural changes in current practices of planning and executing development projects. All Arab countries are undergoing rapid social and economic change. Ministries, institutions, industrial installations, and transport systems are all being developed at a high rate. But many developmental projects are being executed in a manner that does not utilise existing technical skills or institutions. This leads to a low level of employment generation within the Arab countries themselves. An interesting comparison provides an indication of the extent of this fact: Imperial Chemical Industries (ICI) provides direct and indirect employment in the UK comparable to that of the hydrocarbon sector in the Arab world; but the sales of Arab oil are roughly ten times those of ICI. Obviously the only way in which the five million graduates in the applied and basic sciences are going to find employment is if the present technological dependence is reduced through the use of indigenous firms and institutions. Technology policies will certainly assume increasing social and political importance during the next two decades. The very stability of Arab countries will depend on the development of employment-generating technology policies.

A profound religious and ethical rejection of the stark contrast between wealth and poverty pervades the Arab world. This has so far led to the establishment of a number of Arab funds (national and regional) that aim to assist sister countries in their development. Finally, the difficulties and mechanics of development are becoming clearer, the social and political cost of inaction is growing increasingly evident, the enormous resources of the Arab world are gradually coming under the control of local institutions and governments. What, when and how a zipper action will operate to cohere all of these disjointed resources is difficult to forecast. But when it does happen the scientific communities of the Arab world will be called on to play a leading role. □

Mountains out of molehills

KENNETH MELLANBY

One of the less attractive habits of our species, *Homo sapiens* (sic), is the way in which we attribute our unpleasant behaviour patterns to other animals. Thus the human glutton is described as a pig or a hog, and the term swine is used to cover a multitude of our sins. Male chauvinists are pigs, and their women bitches when they assert their rights, cows when they do not, and cats when they criticise other women. Occasionally diminutives like kitten are used more affectionately, but as a rule the comparison with an animal is a derogatory one.

1979 has been called 'The Year of the Mole' — with the mole cast as the villain of the piece. Thus while the majority of viewers could not make head or tail of the BBC television serial *Tinker, Tailor, Soldier, Spy*, they did understand that there was a traitor high up in the security organisation who was passing vital information to the enemy — in other words, a 'mole'. This programme had hardly left our screens when we had the real life case of Anthony Blunt, a distinguished art historian and advisor on pictures to the Queen, who confessed to having been a Communist agent passing information to the Russians when he was attached to the British secret service. He was the mole *par excellence*. Then for some years British Leyland, the ailing motor manufacturer, has had its troubles exacerbated by the actions of a Communist shop steward, commonly called the 'red mole'.

Yet the furry little insectivore *Talpa europaea*, has little in common with a spy or a disruptive agitator. It must be admitted that it is equally unlike the loveable and friendly animal featured in Kenneth Grahame's delightful children's book *The Wind in the Willows*, and presented so vividly on stage in London each Christmas by the redoubtable octogenarian actor Mr Richard Goolden in the play *Toad of Toad Hall*. Moles do indeed live underground in burrows, but their most striking characteristic is their solitariness. Rudyard Kipling wrote, in this case with reasonable accuracy, about 'The Cat which Walked Alone', but the mole is very much more independent than the most self-centred domestic pussy.

In fact it is difficult to see anything in the life history of the mole in common with that of a spy. For almost the whole of their lives, both males and females occupy their own separate sections of underground tunnell, and spend the time in sleep or in running up and down picking up worms and insects which have dropped into the burrow. Should a mole be foolish enough to invade another's territory, it is usually driven off at once. Except for a brief period once a year when the female accepts the attentions of the male, when mole meets mole there is at once open hostility and even bloody combat. There is nothing subtle, deceitful or underhand in the behaviour of *Talpa*.

Gardeners who suffer from the appearance of molehills on their carefully manicured lawns may perhaps be excused for saying nasty things about the culprit, but at least they must admit that by making its presence so noticeable the burrower is hardly being secretive or underhand. So should we not try to find some other zoological sobriquet for a traitor or an industrial troublemaker? I fear that any suggestions will arise the wrath of some other mammalologist involved with the libelled species.

Finally, I find that I am, unwittingly, involved in an attempt to cash in on the current interest in moles. I read in the London newspaper *The Financial Times* that: "Collins the publishers tell me that they have had some discussions about expanding the title of Professor Kenneth Mellanby's book *The Mole* to *The Mole — the Blunt Truth*".

CORRESPONDENCE

Dismissal of Professor Scheer was justified

SIR, — As a member of the federal state government of Bremen I would like to make the following remarks to correct the letter from Uwe Lahl and W. Thiemann of Bremen University (27 September, page 252).

The Senate of the Freie Hansestadt Bremen, the federal state government, has not pursued the dismissal of Professor Jens Scheer from the Bremen civil service because of his political and scientific activities involved with his criticism of the nuclear politics of the Federal Republic of Germany. The Freie Hansestadt Bremen, even the Senate itself, is in fact taking a decidedly critical position regarding the nuclear politics of the Federal Republic of Germany.

Nor has the Bremen government pursued the dismissal of Professor Scheer primarily because he belongs to a non-prohibited political party (the KPD; the Communist Party of Germany). The real reason which has tipped the scales towards disciplinary action against Professor Scheer is rather as follows.

Professor Scheer advocates in public and in Bremen University, while practicing his public duties and abusing his official position, the removal of our free democratic constitutional state of the Federal Republic by violence, and the erection of the dictatorship of the proletariat in its place; this in reality would be the dictatorship of a small elite. In making this aim (of violence) the declared object of his public service activities he abuses the official position given to him.

By the way Professor Scheer has advocated the use of violence not merely verbally, he has already been sentenced for taking part in violence against persons dissenting from his political opinion.

Therefore one cannot reasonably talk about the Bremen State trying to bring scientists under political control by this disciplinary action. Professor Scheer can make use of his constitutional rights in every allowable way. But he cannot legally claim the violent destruction of this state, and at the same time accept payment by the state. All civil rights remain guaranteed to Professor Scheer as a citizen and a scientist of this republic.

The Bremen state government is anxious to learn from German history. The first German Republic of Weimar allowed civil servants to challenge the state which they were sworn to serve, and in the end even to bring about its ruin. The Federal Republic of Germany and especially the German Social Democrats to which I belong have learned their lesson from Weimar.

Finally, the statement "He was not allowed a complete defence" is spun out of thin air. He and his lawyer had every opportunity to plead their position, and they did use it.

Yours faithfully,

FRANKE

Freie Hansestadt
Bremen, FRG

The Sirius Mystery

SIR, — Readers of *Nature* may well be aware from the review of my book *The Sirius Mystery* in the issue of 17 June, 1976 (pages 617–8), that "the problem of the remarkable knowledge of the Dogon people of Mali", referred to by Michael Rowan-Robinson in his review of Carl Sagan's *Broca's Brain* (8 November, 1979, pages 176–7), was first brought to public attention by myself. Although in his review Rowan-Robinson does not mention me by name, and in his book Sagan barely refers to my seminal position with regard to public knowledge of this material except in passing, anyone truly interested in this subject is perfectly aware that they are referring to myself when discussing this matter.

It would be inappropriate for me to discuss Sagan's own errors here. But I would like to reply to statements made by Rowan-Robinson, who says that "Sagan has performed a useful service in collecting together examples of public gullibility and demonstrating how a mixture of deliberate fraud and uncritical thinking has allowed millions to be bamboozled . . .". He says this immediately after discussing my material.

I strongly object to the inference that I have been guilty of fraud in bamboozling a gullible public, and as for "uncritical thinking", the many serious and thoughtful reviews of my book in this very journal as well as others of distinction testify to the fact that although the implications of my work have aroused controversy, it is not widely thought, nor do I obviously think myself, that "uncritical thinking" is a fault of which I have been obviously guilty, especially as my conclusions were all explicitly hypothetical.

The anthropologists who have spent the 48 years from 1931 living with the Dogon tribe are agreed that the knowledge of the Sirius system which they possessed could not have come from Europeans, who in any case had themselves only discovered the superdense nature of Sirius B in about 1926. Knowledge of Sirius B amongst the Dogon goes back hundreds of years, as shown by physical evidence, some of which was even held up in front of television cameras by Dr Germaine Dieterlen, who insisted that it was 400 years old, and said that the European contact theory (espoused by Sagan) was "absurd".

But I do not wish to open this controversy again here. It is in the context of saying that Sagan has shown that the Dogon information "could all have been learnt from contacts with Europeans" (which is untrue) that Rowan-Robinson does me less than justice by saying this is better than it having "been learnt from little green men in UFOs". I have never at any time suggested this; I went out of my way in my book to say that I do not believe that UFOs are extraterrestrial craft of any kind, or connected with my subject, and Rowan-Robinson's remarks are therefore a slur against my intelligence and quality of work which I most strongly resent.

Rowan-Robinson also betrays an indefensible bias against the serious possibility that our planet has at some time in its history been visited by intelligent extraterrestrials. What is so remarkable about this *per se*? Are we so incapable of speculating about these matters that we deny them solely because such a visitation seems to us extraordinary? The electric light bulb would have seemed extraordinary to Plato and Aristotle, but does that rule out the possibility of its eventual invention? This is the kind of inverted logic demonstrated by those whose minds are too small for large notions.

Yours faithfully

ROBERT K.G. TEMPLE

Sutton Mallet, Bridgwater, Somerset, UK

Standardisation of reference citation

SIR, — A significant part of a scientist's time is spent in drafting manuscripts for publication. Part of this task involves the careful listing and checking of references. At present, most journals have their own distinctive style and even basic references have to be rearranged with considerable waste of time and effort as every new paper is drafted. Some idea of the variability of reference citation can be seen if the bibliographies of the following internationally recognised marine science journals (first published in sequence between 1953 and 1979) are examined: *Deep-Sea Res., Mar. Biol., J. exp. mar. Biol. Ecol., Estuar. Cst Mar. Sci., Oceanol. Acta., J. Plankton Res.* One conclusion that can be drawn from such an examination is that the variability of reference citation is increasing with time.

Some progress has been made towards international standardisation with the introduction of the following international standards: ISO 4-1972 (E), Documentation — International Code for the Abbreviation of Titles of Periodicals and ISO 833-1974, Documentation — International List of Periodical Title Word Abbreviations. (See also BS 4148 Part 1: 1970 and BS 4148 Part 2: 1975.) The establishment of this international standard for over five years does not seem to be acknowledged by many editors (including *Nature's*) who still recommend the fourth edition of the *World List of Scientific Publications* for journal abbreviations, a list which was last published in 1963 to 1965! In the absence of a properly updated world list and prior to the publication of the new international standard,some journals (such as *Journal of the Marine Biological Association of the United Kingdom*) have reverted to printing the full titles of journals.

There is so far no international agreement on bibliographic references, rather the opposite, as the American National Standard ANSI 239.29-1977 and British Standards BS 1629:1976 and BS 5604:1978 differ considerably from each other in their recommendations and from each of the journals cited above. Major differences between the two national standards are the use of capitals, italics and bold face in the British Standard in contrast to a single type face and more complicated punctuation rules in the American standard. The 'Harvard' system with the year of publication following the author and a form of the 'Numeric' system as used in *Nature* are the two formats recommended in the new British Standards BS 5605:1978 which was specifically prepared for editors and authors of articles in journals and books. The 'Harvard' format comes closest to that now used by most journals. The simpler punctuation of this standard is also preferable, although the adoption of a simple typeface as used in the American system may be more compatible with computerisation of references.

A standard for abbreviated references, as used for instance in *Nature*, is only given in ANSI 239.29-1977 restricting information to the journal title, volume number, pages and year of publication. This is not sufficient for scientific journals as one needs to assess immediately the 'pedigree' of a particular piece of work by reference to the original authors and if possible an abbreviated title.

Publication of an international standard for bibliographic references in scientific journals is overdue. Major publishing houses, editors of journals and scientists should be consulted in this standardisation process as well as librarians and national standardisation authorities.

Yours faithfully,

P.C. REID

NEWS AND VIEWS

Pain, enkephalin and acupuncture

from Shin-Ho Chung and Anthony Dickenson

DURING the past few years, there have been enormous strides in understanding the neural mechanisms underlying the perception of pain. From what we now know, it is easy to see why the mechanism of pain perception has remained enigmatic for so long. Unlike the other senses, there seem to be no cortical centres which are solely devoted to processing pain, nor is there a discrete fibre bundle, which can be severed to alleviate chronic pain. Indeed, the system seems to be elaborately designed to ensure that it is fail-safe, with an added feedback loop which, when activated, reduces the intensity of persistent pain.

It is now firmly established that small-diameter fibres, whose endings are distributed throughout the body, including skin, muscles and viscera, respond specifically to painful stimuli. These fibres, on entering the spinal cord, branch profusely and form synapses in the superficial layers of the dorsal horn, mainly in the marginal zone and the substantia gelatinosa[1]. Here the fine terminals of axons and dendrites, together with collaterals of ascending and descending fibre tracts, form a dense jungle of neuropil, the precise wiring diagram of which has yet to be elucidated. There are two distinct groups of spinal neurones which respond to painful stimuli, one located in the superficial layer (lamina I) and involved mainly in transmitting sharp pain, and the other in the deeper layers of the dorsal horn (laminae IV and V) responding to intense pain[2]. Through a dense meshwork of short and long axons, these cells transmit messages further centrally. Some of these axons terminate within the spinal cord[3], whereas others ascend to the brainstem reticular nuclei[4]. The longest bundle proceeds to the thalamus[5,6], accompanied by other axons arising from the brainstem. In stark contrast to the other senses, the neural organisation of the pain system is characterised by elaborate feedback networks. Terminals of at least three descending fibre tracts, which originate from the brainstem nuclei, form synapses in the dorsal horn[7]. In addition numerous short axons of spinal neurones traverse a few segments, their terminals interlacing with the dendrites of pain cells located further rostrally[1].

The interplay between the incoming pain messages and the descending influence from the brainstem has recently been the focus of intensive investigation. In 1964 Taub[8] first discovered that spinal neurones responding to painful stimuli could be silenced when certain areas of the brainstem were stimulated electrically. This initial finding of descending inhibitory pathways, confirmed subsequently by others, has recently been extended. The physiological effect on spinal neurones of electrical stimulation of the brainstem is now known to be confined to cells responding to pain, especially those in laminae IV and V[9-11]; other neurones nearby which convey, for example, information concerning touch or temperature, are uninfluenced by this manoeuvre. Careful mapping has revealed that there are discrete nuclei in the brainstem, stimulation of which produces potent neuronal inhibition and behavioural analgesic effects; among these are the nucleus raphe magnus and the periaqueductal grey[10-13]. The raphe magnus is known to be the origin of certain descending fibre tracts[14,15], but the periaqueductal grey, which is located along the length of the aqueduct, seems to exert its influence indirectly on the dorsal horn through the nucleus raphe magnus[16,17].

The analgesic effect of morphine and related compounds can now be understood in terms of their inhibitory influence on the transmission of pain. For reasons which are not yet entirely clear, morphine reduces the efficiency of synaptic transmission between pain fibres entering the spinal cord and their target cells in the dorsal horn[18-20]. A small quantity of morphine injected into the substantia gelatinosa reduces sensitivity to pain, when tested either behaviourally[21] or electrophysiologically[22]. The action of morphine, however, is also mediated by the descending inhibitory system of the brainstem. From numerous studies involving gross lesions, microinjection of morphine, and biochemical mapping of the distribution of opiate receptors, the same conclusion emerges; the cells in the periaqueductal grey and the nucleus raphe magnus, richly endowed with opiate receptors, detect the presence of morphine and transmit this message down to the dorsal horn of the spinal cord[23,24]. Here the terminals of the descending fibres release serotonin[25], which, through mechanisms yet to be discovered, interferes with the excitatory synaptic processes between the primary pain fibres and spinal neurones[26]. This inhibitory modulation on the transmission of pain, the essence of Melzack and Wall's 'Gate Theory'[27], relies entirely on the integrity of the brainstem descending system. If, for example, the raphe magnus or the periaqueductal grey are destroyed, or naloxone (a specific opiate antagonist) is injected into these brain areas, then the analgesic effect of morphine is drastically reduced[23,28-30]. Moreover, both the neuronal inhibition and the behavioural analgesia induced by electrical stimulation of the raphe magnus are reduced by naloxone[31,32]. Why, of all other substances, opiates and opiates alone turn out to be such potent pain-killers is one of the deep mysteries of the brain.

While the neural basis for analgesia was beginning to be understood, two related pentapeptides, known as Met-enkephalin and Leu-enkephalin, were isolated from the brain. These opioid substances, along with other related peptides containing the enkephalin sequence, are present in axonal endings of both central and peripheral nerves. They bear a stereochemical resemblance to opiates and are known to be synthesised locally. Biochemical and immunohistochemical analyses have revealed that those parts of the nervous system directly involved in mediating or modulating pain are especially rich in both opiate receptors and the endogenous opioid substances. Since these discoveries, some of the electrophysiological and behavioural findings obtained with morphine and electrical stimulation of the brainstem have been replicated with

0028-0836/80/03243-02$01.00

enkephalins[33,34]. All the findings to date show that the action of morphine can be mimicked by enkephalins. Some problems remain however. We want to know, for example, where on the neuronal membrane opiate receptors are located and how the peptides influence the receptors to generate synaptic currents.

If the brainstem inhibitory nuclei are activated by naturally occurring opiates as a result of injury, would it not be possible to mimic this by stimulating peripheral nerve fibres carrying pain messages and so reduce the intensity of persistent pain? The technique of acupuncture, which the Chinese have traditionally used for combating pain, seems to be based on this principle. In a series of elegant studies, Le Bars and his colleagues[35,36] have demonstrated that cells in lamina V of the spinal cord responding steadily to painful stimuli applied to the hind limb can be silenced by activating, either with natural or electrical stimulation, pain fibres from other parts of the body. These lamina V cells are the ones that respond to intense pain, and the reduction of their activity is brought about by the descending inhibitory system from the brainstem and also can be mediated by opiates[37]. On the other hand, the activity of some cells can be inhibited by the local circuitry within the spinal cord[27,38], without involving the brainstem.

Thus, it is now becoming clear that the analgesic effect of acupuncture is the result of interaction between impulses from the origin of pain and afferent impulses from the acupuncture point[39], and that this interaction takes place at different levels of the central nervous system[40]. For acupuncture to be effective in relieving pain, however, the involvement of the nucleus raphe magnus and endogenous opiates is required. There are several independent lines of evidence for this assertion. Pomeranz and his colleagues[41,42] have shown that the analgesic effect produced by acupuncture in animals is abolished if naloxone is injected. Several clinical studies also note that strong acupuncture is most effective for alleviating chronic pain in humans[43–46], and the analgesia so produced is antagonised by injection of naloxone[43,45,47]. In retrospect, it is clear that the Chinese have been at the forefront of research into pain. They have known for several years, that the nucleus raphe magnus[48], the serotonergic system[49], and inhibitions of lamina V cells[50] are intimately involved in producing the analgesic effect of acupuncture. To the Western mind, it has been inconceivable until now, exactly how placing a single needle into a certain point of the body could produce such a potent amelioration of pain elsewhere in the body.

There is a glimmer of hope that, in the near future, new methods of controlling pain and new analgesics without addictive properties may be found. But the fundamental question of how we perceive pain still remains to be answered. Pain, after all, is a conscious awareness, and so involves the full participation of higher cortical centres. On the role of the cortex in perceiving pain, we remain totally ignorant. It is towards the elucidation of the interaction between perception and transmission of pain that future research must be directed. □

Footprints of the Sun

from Bevan M. French

WHAT has the Sun been up to lately? The question is becoming important both scientifically and socially, as more evidence appears that the Sun is (and has been) a variable star. Astronomers worry about the Sun's variability as a clue to understanding stellar behaviour. Everyone else is (or should be) concerned about what future solar variations might do to our weather, climate, food production, and civilisation. Understanding the Sun's past may help us predict its future behaviour a little better.

Where are the records of the Sun's past? Almost everywhere in the Solar System, if the results presented at the Conference on the Ancient Sun last October*, are any indication. Traces of solar behaviour have been left on many worlds, and the list of materials that hold assorted obscure parts of the record reads like a planetary jumble sale: historical documents, tree rings, pollen collections, deep-sea sediments, glacial deposits, spacecraft measurements, Marine and Viking photographs of Mars, polar ice cores, Apollo lunar samples, and meteorites. In each material the solar record, while readable, is often incomplete, ambiguous, or model-dependent. A greater problem in putting the pieces together is the lack of communication between the unusually wide range of specialists involved — solar astronomers, historians, nuclear physicists, glaciologists, tree-ring daters, and the geologists, geochemists, and physicists involved in moon rock and meteorite studies.

The goal of the Conference was communication: to introduce each participant to the data available from other fields. It succeeded extremely well. Solar astronomers described for geologists the current state of theories (or the lack thereof) about how the Sun works. Others reviewed the information about solar variability that has been extracted from terrestrial climate records, from historical records, and from lunar samples and meteorites. These reviews set the stage for detailed examinations of solar variability over three timescales: short-term (0–10^2 yr), intermediate (10^2–10^5 yr), and long-term (10^5–10^9 yr).

There is clear evidence of short-term variability in the present-day Sun, even though detailed records of such things as solar flare activity and the solar constant (S) go back less than 50 years and reliable sunspot records cover less than two centuries. Short-term (hours to days) changes are observed in the solar radio, ultraviolet, and X-ray outputs (W.J. Borucki, NASA-AMES Research Center; P.V. Foukal, AER Inc., Cambridge, Massachussetts), and in the flux, velocity, and He/H ratio in the solar wind (A.J. Hundhausen, HAO, Boulder). Variations in the composition of solar flare particles have been measured by spacecraft (R.A. Mewaldt, Caltech, Pasadena), and measurements of lunar samples indicate significant variations in the proton flux on the order of decades (R.C. Reedy, Los Alamos Scientific Laboratory). The modulation of galactic cosmic rays by the 11-yr-cycle of the solar activity has been known for some time, but studies of cosmogenic radioactivities in meteorites that fell during the period 1967–78 (J.C. Evans, Johnson Space Center, Houston) indicates that the modulation is about three times as intense as expected. Despite these variations, the solar constant (S) has apparently remained constant to within about 1%, but recent spacecraft measurements suggest that variations of a few tenths of a percent have actually been detected. Even such small changes have significant effects on the Earth's climate.

---

*Held at Boulder, Colorado on 16-19 October 1979. A limited number of abstract volumes are available from: Administrative Office, Lunar and Planetary Institute, Houston, Texas 77058 USA. US requests should include \$2.00 to cover handling and mailing costs. Non-US requests should include \$1.05 for return by surface mail, \$4.25 for airmail return. The Proceedings of the Conference will be published in late 1980 by Pergamon Press.

In the intermediate period (10^2–10^5 yr), historical records become spotty, and scientists are dependent on the solar record in natural materials (both terrestrial and extraterrestrial). The Maunder Minimum, a period of reduced solar activity (1645–1715 AD) characterised by a virtual absence of sunspots, has now been well established by a combination of historical records (J.A. Eddy, HAO, Boulder) and ^{14}C studies of bristlecone pine tree rings (M. Stuiver, University of Washington, Seattle); the effects of reduced solar activity at this time may also have been detected in iron meteorites (O.A. Schaeffer, SUNY, Stony Brook). Earlier periods of both reduced and increased solar activity are also seen in the bristlecone pine records back to about 5,000 b.p. (Stuiver).

A debate about possible variations in solar flare intensity during the past 10^4 years has been generated by the record of solar flare particle tracks preserved in rocks and small crystals collected from the surface of the Moon. Comparative counts of solar flare tracks and the microcraters formed by cosmic dust particles suggest that both the dust flux and flare activity have been constant for about 5×10^5 yr (E. Zinner, Washington University, St Louis), but the possibility of higher flare activity about 10^4 years ago is still being considered (H. Zook, NASA Johnson Space Center, Houston). One suggestion of higher flare activity is the excess amount of ^{14}C detected in lunar surface soils (E.L. Fireman, Smithsonian Astrophysical Observatory). This could have been produced by solar flares. The alternative explanation, that the ^{14}C was produced in the Sun and implanted by the solar wind (Fireman), raises theoretical problems about just how ^{14}C is now being made inside the Sun.

Long-term variability (10^5–10^9 yr) involves the problem of what the 'early Sun' was like soon after its formation. Until about a decade ago, this problem area was inhabited entirely by theorists. Now a new group of scientists is extracting information (and even solar particles) from samples that actually saw the face of the ancient Sun — rock breccias from the lunar highlands and tiny crystals that were compacted into meteorites more than 4×10^9 years ago.

To quote James Arnold's (University of California, San Diego) summary of the Ancient Sun: "Things haven't changed an awful lot." G. Crozaz' (Washington University, St Louis) review made the following points: (1) solar flares were active at least 4.2×10^9 years ago and left particle tracks in meteorite grains exposed to the Sun at that time; (2) the solar flare energy spectrum (measured in lunar samples, meteorites, and a glass lens from the Surveyor 3 spacecraft) seems to have been about the same for the last 4×10^9 yr; (3) enrichment of heavy elements at low energies (<10 MeV) is seen in both ancient and modern flares; (4) no convincing evidence for higher solar activity during the early history of the Moon (about 3.9–4.4×10^9 yr ago) has been found in lunar samples; (5) there are no apparent changes in the character of galactic cosmic rays during at least the past 50×10^6 yr.

Along with this reassuring evidence of constancy, there are some surprising variations, for which the main evidence is the analysis of ancient solar wind particles trapped in lunar samples over the past 2–3×10^9 yr. The most puzzling effect is a major variation (about 30%) in the ^{15}N/^{14}N ratio of nitrogen in the solar wind, from about −200 permil 2–4×10^9 yr ago to about +100 permil now (R.N. Clayton, University of Chicago; J.F. Kerridge, University of California, Los Angeles), combined with an excess amount of total nitrogen in the ancient lunar soils. Because the Moon contains virtually no indigenous nitrogen, these variations must arise in the solar photosphere, but there is no agreement, and considerable bewilderment, about how such gross isotopic changes can be produced and why they appear in only a single chemical element.

The Conference made possible an exciting introduction, review, and dialogue about the sun's history. What comes next?

- Reworking of current solar theories to include the hard data now available about the ancient and modern Sun. For example, how are such 'proxy' indicators as sunspots and the intensity, energy, and composition of solar wind and solar flare particles related to overall solar luminosity?
- More and better solar measurements, especially of the solar constant (S) and the solar radius. New space missions such as Solar Polar to observe the Sun, and the Venus Orbiter with Imaging Radar (VOIR) to scan ancient planetary surfaces.
- New analytical methods — accelerator measurement of new cosmogenic nuclides such as ^{10}Be, and ion microprobe studies of ancient solar wind implanted in Moon rocks and meteorites.
- Studies of newly available materials that contain important parts of the solar record: micrometeorite spherules from deep-sea sediments; deep cores of polar ice that go back more than 8,000 years; new collections of meteorites that fell in the Antarctic and were preserved in the icecap, some for more than 10^6 yr; old historic falls of iron meteorites that may actually record the Maunder Minimum; and a wide variety of historical records, especially from Oriental countries, that have never been examined in detail.

If the problems of deciphering the Sun's history are still immense, so are the new materials and techniques now available to attack them. Scientists from many different fields have many challenging and exciting things to do before they meet again to talk about what the Sun has been up to.

Drug metabolising enzymes

from A.E.M. McLean

THE mamalian liver responds to an influx of chemicals by making more of the enzymes that oxidise and conjugate the majority of foreign chemicals. Induction of enzyme synthesis by carcinogenic hydrocarbons was shown in the rat by Alan Conney (Hoffman La Roche, Nutley) more than 20 years ago and he returned to a Ciba symposium in London recently* to describe induction of drug metabolising enzymes in man by dietary factors. High protein diets, charcoal broiled steaks, and brussel sprouts all have potent inducing effects.

Discussion ranged on the relative importance of natural compared with synthetic inducers such as drugs and polychlorinated biphenyls in the environment. The importance of genetic factors compared with environmental inducers in controlling drug metabolism, was brought up by R. Smith (St. Marys Hospital Medical School, London) who presented information about the different products of metabolism of debrisoquine and phenacetin. He pointed out that the same plasma half life for a drug might be, and often was achieved by quite different genetically determined pathways of metabolism, so that it was important to know not only the rate of disappearance of a drug, but what products were formed.

The need to know the fate of toxic materials was a recurrent theme. Only by measuring the exact fate of carcinogenic compounds like benzo (a) pyrene was it possible to see what influence exposure to inducing compounds, which can increase both toxic and detoxicating pathways, would have on toxicity. Most carcinogens require metabolism to their active form before they will attach DNA, and the sweet potato poison, ipomeanol, similarly needs oxidative activation in the Clara cells of the lung before it causes acute lung damage (M. Boyd, National Cancer Institute, Bethesda). The pathways of activation and detoxification are so numerous that it is difficult to predict whether previous exposure to inducers will increase or

---

*The Proceedings will be published as Ciba Foundation Symposium 76 under the title of 'Environmental Chemicals, Enzyme Function and Human Disease' by Excerpta Medica, Amsterdam in Summer, 1980.

0028-0836/80/03245-02$01.00

decrease the toxic effects of other chemicals.

A. Breckenridge (University of Liverpool) described the effect of inducer drugs in rendering low dose oral contraceptives inactive. It is not clear whether brussel sprouts would have the same effect. A. McLean (University College Hospital Medical School) found no detectable effect on mortality of people with epilepsy of the inducing effects of anticonvulsant drugs. He suggested that the next line of investigation in toxicology should be to examine the response of cells to attack by activated toxic molecules. E. Farber (Toronto) also suggested that too much attention had been paid to the chemistry whereby a molecule of toxic material was activated and interacted with cell macromolecules. Not enough thought had been given to the response of the cell. If 10% of the genome was devoted to response to adverse conditions it would be a reasonable proportion, and leave an enormous range of built-in responses to toxic attack. Carcinogenesis might be the end stage exaggeration of such an adaptive response to a chemically unfavourable environment. A system for development of tumour nodules in a few weeks promised to be a favourable model for analysis of the cell response to carcinogens.

T. Connors (MRC, Carshalton) and J. Higginson (IARC, Lyon) started and ended the meeting by reference to the need to bring human and laboratory experience together, the need to understand tumour promotion as well as carcinogen activation, and the need to combine biochemistry and epidemiology. □

The ecology of the footprint

from Peter D. Moore

THE ecological effects of recreational pressures on mountains, sand dunes and wetlands are reasonably well documented, and a great deal of work has been carried out and much has been written on the subject of trampling. What is surprising, in view of this, is that so little is known of the ecology of the footprint.

That the footprint has a distinctive ecology of its own was clearly demonstrated by some accidental experiments of Harper, Williams and Sagar some 15 years ago (*J. Ecol.* **53,** 273; 1965). They were in the process of examining the germination characteristics of three plantain species (*Plantago lanceolata, P. major and P. media*) in open plots, when an oversight led to the trampling of their plots by pigs involved in other experiments. Groups of *Plantago* seedlings appeared wherever a hoofprint had been made. Evidently the alteration of microtopographic, and hence microclimatic and microhydrological features of the soil surface by the impact of the hoof, had strongly influenced the germination and establishment of the plantains. Harper *et al.* developed these observations into a series of experiments in which they confirmed the importance of microtopography in seed and seedling behaviour.

Since then, many attempts have been made to examine the microclimatological changes associated with trampling, both above and below the soil surface. A range of soils, from chalk (Chappel *et al. J. appl. Ecol.* **8,** 869; 1971) to sand (Liddle & Grieg-Smith *J. appl. Ecol.* **12,** 893; 1975) have been looked at. But in these studies the emphasis had changed from the single footprint to the overall influence of continuous trampling in creating tracks and paths.

One habitat in which the individual footprint survives and remains a scar on the surface for a considerable time is the *Sphagnum* bog. All mire systems are sensitive to trampling for, instead of a mineral soil being compressed, the plant body itself and the organic detritus underlying it, receives the direct impact of the foot. Relatively deep depressions are formed which may fill with water, modifying the microenvironment and creating small scale pool successions. Slater and Agnew (*Biol. Conserv.* **11,** 21; 1977) have investigated the development of footprints at Borth Bog in west Wales. They estimated that the 1,890 visitors to the bog each year (mainly researchers and students) displaced a total of 4,228 m^3 of the bog surface by trampling. Taking a single footprint, about 50% of the displaced volume was restored in the first month, largely by the elastic response of the bog moss carpet. Subsequent recovery was far slower, being about 90% complete only after 18 months; often it took 30 months for all traces of the footprint to disappear. One species which seemed particularly well adapted to colonisation of disturbed sites was the white-beaked sedge (*Rhyncospora alba*), which, the authors contend, may increase the susceptibility of the vegetation to fire, adding to the ecological complications caused by trampling.

A further example of the distinctive ecology of the footprint has now been reported from the edges of a glacier in northern Norway by Theakstone and Knighton (*Arctic Alpine Res.* **11,** 353; 1979). The level of a lake at the outlet of the Austerdalsisen glacier has been lowered 70 m by the construction of a flood control tunnel, and the sediments exposed are now being invaded by terrestrial vegetation. The footprints of reindeer and man in the exposed silts have become colonised by the moss *Aongstroemia longipes.* The depressions are 1-2 cm deep and were first created in the summer of 1976. The colonisations observed in 1977 have persisted into 1978, the moss patches still displaying the shapes of the original foot or hoof prints. One suggestion is that the ponding of water in these hollows may have provided the appropriate hydrological conditions for the moss to establish itself. It is interesting to note that the first British report of *Aongstroemia longipes* was in the Ben Lawers area following soil disturbance as a result of dam construction (Crundwell, *Trans. Brit. Bryol. Soc.* **4,** 767; 1955).

Evidently the ecology of footprints warrants further study. Such research may confirm the old maxim that one plant's depression may be another's opportunity.

Transformation and tumorigenesis

from R.E. Langman

AT a recent workshop on transformation mechanisms* M. Cohn (Salk Institute) opened with a plea that the meeting address the question of how many genetically determined events are required to convert a cell from the normal to transformed (tumorigenic) phenotype in the absence of any host surveillance mechanisms. In practical terms the change from anchorage-dependence to anchorage-independence (that is, the cells form colonies in agarose) is almost universally accepted as the assay for transformation. But we know virtually nothing about why colony formation in agarose indeed correlates so well with tumorigenicity, except to note that lymphohaemopoietic cells also normally grow as colonies in agarose, and are not obviously transformed or tumorigenic *per se*. In seeking possible generalisations, Cohn argued that there were few ways a cell could become transformed, one linked to anchorage-independence for non-haemopoietic cells, the other linked to whatever causes lymphohaemopoietic transformation.

I. Weissman (Stanford University) showed that individual lymphoma cell lines from mice produce a virus that binds specifically to that lymphoma, and monoclonal antibodies which block virus binding also block cell growth. Thus, it was argued in this case that virus, by perhaps acting like an antigen, provides the proliferative stimulus for the cell it infects. In general then one might view the lympho-

haemopoietic cells as anchorage-independent by differentiation, but geared to require constant signalling for continued growth, as seen in this viral lymphoma example.

Using the DNA 'transfection' technique, B. Shilo (Massachusetts Institute of Technology) showed that DNA from several cell lines transformed with carcinogens could cause 3T3 fibroblasts to acquire the fully transformed phenotype of anchorage independence and tumorigenicity. The frequency of 'transfection' in these experiments is consistent with the idea that a single dominant gene is responsible for the transformed phenotype; this had been shown previously in the majority of cell hybridisation experiments. Furthermore, transformation of normal recipient cells with the transferred DNA was associated with a unique restriction fragment of DNA. Thus one, or a cluster of tightly linked genes is capable of dominantly causing the expression of the transformed phenotype. The analysis of this 'transforming' fragment and the characterisation of the protein product (if any) will be awaited with interest.

It is well established that the *src* gene of avian sarcoma viruses such as Rous sarcoma virus (RSV) is necessary for expression of the transformed phenotype. As yet it is not quite proven that the *src* gene product alone is sufficient, but the available evidence strongly points in this direction. The 60,000 molecular weight (60K) protein now thought to be coded by the *src* gene is a protein kinase and is very similar to a host cell protein kinase. T. Hunter (Salk Institute) showed that an *in vitro* rabbit reticulocyte protein synthesising system primed with RSV RNA produced a 60K protein that is indistinguishable from the protein identified in RSV-transformed cells. It was also shown that the 60K Src protein is a tyrosine kinase, and that in normal cell extracts phosphotyrosine is a minor component of the phosphorylated amino acids, but that after RSV transformation, the amount of phosphotyrosine, relative to phosphoserine, was increased 5-10 fold. A. Levinson (University of California, San Francisco) reported that the 60K Src protein is tightly bound to, and therefore probably integrated into, the plasma membrane. After mild proteolysis a 56K protein is found free from the membrane, and retains the kinase activity. Attempts to label the 60K Src protein on the outside of the cell have been unsuccessful up to now, and indicate that it is attached to the inside of the plasma membrane. As the Src protein kinase is very similar to the normal cell kinase but is distinct both structurally and in its kinase activity, the suspicion is that the viral Src product initiates transformation by radically upsetting the regulatory functions of the normal cell 'Src' kinase. How this upset of kinase activity leads to transformation is not clear, except that Src protein is required continuously for the expression of the transformed phenotype, as evidenced by temperature-sensitive mutants of *src*.

Although the Abelson leukaemia virus (ALV) lacks an identifiable *src* gene, O. Witte (Massachusetts Institute of Technology) showed that a 120K protein with tyrosine kinase activity is produced from the ALV genome. This kinase differs from the RSV kinase in that it requires Mn^{2+} instead of Mg^{2+} cations, but is similar inasmuch as there is in murine bone marrow cells (the preferred viral target *in*

Palmdale bulge: fact or fiction?

from Peter J. Smith

SOME curious things have been happening to southern California recently; so much is certain. The only problem is that the curious phenomena that everyone thought were taking place may not have been taking place at all, whereas some quite different curious behaviour may have been going on. Or, what appeared to be certain facts with uncertain explanations now seem to have been uncertain facts with even more uncertain explanations.

Bits of the story have been coming out at intervals for several months now, although the full extent of the problem only become clear at last month's meeting of the American Geophysical Union in San Francisco. The most startling piece of experimental evidence was presented by A.E. Niell of NASA's Jet Propulsion Laboratory, who reported that the distance between his Pasadena laboratory and NASA's Goldstone Deep Space Station some 193 km to the northeast had increased by 20.3 cm in just 7 months. This remarkable measurement was made by repeatedly recording radio noise from quasars simultaneously at the Pasadena and Goldstone radio telescopes, a procedure that can give distance changes between the telescopes to within ± 5 cm; but the expansion has been confirmed in general terms by laser ranging experiments carried out independently by the US Geological Survey. According to J.C. Savage and W.H. Prescott, laser measurements show that between 1974 and 1978 southern California was undergoing a nearly uniform contraction in the north–south direction but that since 1978 there has been east–west expansion with little or no north–south compression. So the laser data for the post-1978 period are consistent with the 1979 radio interferometry.

Unfortunately, however, the laser data as a whole seem not to be in agreement with the behaviour of the so-called Palmdale bulge, the 84,000 km^2 area of southern California which covers the southwestern section of Niell's interferometry baseline and which has undergone well-publicised ups and downs over the past 20 years. The rise of this zone apparently began in 1959, although this was not discovered until 1976 when it immediately set off speculation about an impending earthquake. By 1974 the maximum uplift had reached 45 cm; but since then there has been a remarkably rapid deflation accompanied by a tilt of the whole region to the north, an increase in the horizontal strain and an increase in radon emission — a group of phenomena which has again sparked off seismic speculations. The strange thing is, however, that the behaviour of the bulge is inconsistent with much of the laser-derived information about the larger area. When southern California was undergoing north–south contraction from 1974 to 1978, a simultaneous east–west or vertical expansion was to be expected. But during this period the bulge was actually contracting, which it continued to do even when the north–south contraction stopped. As Barry Raleigh of the US Geological Survey recently noted, "no physical model has yet been proposed which incorporates these apparently inconsistent results."

And maybe no model is necessary, for what if the observations are wrong or perhaps, let us say, not quite what they appear to be? After pouring more than $1 million into the study of a supposedly deflating bulge, this may seem an odd point to make; but D.D. Jackson and W.B. Lee made it at San Francisco in all seriousness. From an examination of the data going right back to 1959, especially those along the profile San Pedro — Los Angeles — Saugus — Palmdale, Jackson and Lee conclude that most, if not all, of the rise centred on Palmdale never in fact took place at all. They find that the altitudes of larger features such as mountains, as indicated by the raw observations, have changed by the same amounts and at the same times as those of the smaller features such as ridges; and although a tectonic cause for such behaviour cannot be ruled out completely, the simplest explanation is the presence of a systematic error, probably in the calibration of the levelling rods.

Many people are simply not going to believe that, at least without much more evidence, if only because of the embarrassment it would cause. Yet there is clearly something going on in southern California. Monitoring continues.

Peter J. Smith is a Reader in the Department of Earth Sciences at the Open University.

0028-0836/80/03247-01$01.00

vivo) a 120K tyrosine kinase with properties very similar to the viral kinase. Although this extends the generality of tyrosine kinase activity as a crucial factor in transformation, it is clear that the small DNA tumour viruses such as SV40 and polyoma lack identifiable kinases. T. Benjamin (Harvard University) noted that mutants in the *hrt* gene region in polyoma virus, which overlaps with the regions encoding the big, middle and small 'T' antigens, showed decreased levels of histone acetylation compared with wild-type polyoma. All these findings on viral transformation together point to several pathways leading to an ultimate transformation site, and to the ability of different viruses to tap into these different pathways to yield the same overall result.

Returning to the opening question of how many genetic events are required for expression of the transformed phenotype, it seems clear that one is a possibility, but that how many different events can give this apparently single gene change is less clear although one must suspect that it is greater than one. Epidemiologists have argued for multistage models of *in situ* tumorigenesis, especially for carcinomas where a minimum of between four and six steps is predicted. If one (dominant) or two (recessive) gene level events can give rise to *in vitro* transformation, then the suspicion must be that the remainder of these steps are either spurious because of assumptions about the data and its relation to tumorigenesis, or are due to evasive steps a transformed cell must take in order to survive various surveillance mechanisms.☐

Polarised electrons are going round in circles

from C. B. Lucas

SPIN-polarised electrons are of interest to physicists and biologists at both the high and low ends of the particle energy spectrum. Several recent advances have provided new sources of polarised electrons, and should provide new insights in fields such as neutral currents, surface physics and molecular optical activity.

One way of producing spin-polarised electrons is to take a storage ring, fill it with electrons or positrons, and leave for an hour or so. This recipe for polarising electrons by macroscopic means seems contradictory to long-standing arguments that they cannot be so polarised, for example by passage through a Stern-Gerlach magnet. In that case, the splitting of the beam after passing through an inhomogeneous magnetic field is less than the uncertainty in their position as given by Heisenberg's principle.

However the polarisation mechanism is easily understood if one remembers that an electron orbiting in the magnetic field of a storage ring and emitting synchrotron radiation may flip its spin on emitting a photon. The probability of a transition depends on the spin direction relative to the guiding magnetic field, the positrons becoming polarised in the direction of the field, the electrons in the opposite direction. Since the probability of a spin-flip emission is typically only 10^{-11} that of a normal emission, the polarisation builds up very slowly.

The polarisation effect was first predicted by Ternov, Loskutov and Korovina as early as 1961. Two years later it was shown that, in a typical storage ring, the transverse polarisation should build up in a period of about an hour to a limiting value of 93.4%.

The first experimental confirmations of theoretical predictions were made on electrons in the storage rings at Novosibirsk and Orsay in 1971. In the former, at an energy of 640 MeV, approximately 50% polarisation was measured after about 100 minutes, compared with a calculated value of 66% when depolarisation effects were included. Since then, measurements on several of the world's storage rings have been made, confirming these results, and 76 ± 5% polarisation has been reported from Stanford. (The latest position was discussed at the Argonne conference on High Energy Physics with Polarised Beams and Polarised Targets (*AIP Conference Proceedings* No 51, ed. G.H. Thomas, 1979)).

Another example of a circular approach to this problem is the latest experiment to produce polarised electrons by photoionisation with circularly polarised light. This process is known as the Fano effect, after its originator. In this case, polarised electrons are produced by transfer of angular momentum from the photons to the electrons. The first Fano-effect studies were made in the near ultraviolet with caesium, and were remarkable in producing electrons, almost completely polarised, with wavelengths close to a minimum in the photoionisation cross section.

Measurements in the vacuum ultraviolet require more sophisticated optical techniques. Measured polarisation at wavelengths longer than 140 nm ranges from a maximum of about 50% in thallium to, typically, a mere 15% in lead. Molecules have been even more disappointing, yielding no significant polarisation of the photoelectrons.

Nevertheless measurements have been continued further into the vacuum ultraviolet, at around 100 nm, by a group using the radiation produced by the synchrotron running at 800 MeV at the University of Bonn (*J. Phys. B* **12**, L679; 1979). Preliminary measurements showed that the radiation above and below the plane of the electrons was respectively left and right circularly polarised to at least 80%. When used to ionise xenon, circularly polarised photons produced electrons which were polarised up to 75%, in general agreement with theoretical predictions. Though still not so impressive as the very first measurements in caesium, these results are comparable with the polarisation which could have been obtained if the electrons in the synchrotron had been injected into a storage ring, though the current would then have been many orders of magnitude greater. Hence polarised electrons in a storage ring could be used to produce polarised photoelectrons through the synchrotron radiation! This means that the particle physicist is rapidly losing his interest in the polarised electrons produced by the atomic physicist, since the former has a very intense source of highly polarised energetic electrons (and positrons) accidentally at his disposal; this provides the opportunity to study directly the neutral weak current phenomenon.

The atomic physicist can unfortunately make little use of polarised electrons or positrons at such high energies, and the laws of electron optics prevent a useful well-defined low energy beam from being obtained from one of much higher energy. Of interest, therefore, is the report by a group at the University of Michigan (*Phys. Rev. Lett.* **43**, 1281; 1979) that 1 eV positrons have been produced with at least 20% polarisation. The authors suggest that the principal use of this source to the physicist will be for the study of polarised low-energy positron diffraction from surfaces. For the biologist, interest in this source is connected with the controversial hypothesis that the origin of biomolecular optical activity might be linked to the polarisation of β-particles from radionuclides.

Interest in spin-polarised electrons is burgeoning as the number of different mechanisms for their production has increased rapidly in the past decade; previously, only elastic electron scattering by heavy atoms looked at all useful. Production of polarised electrons by the use of lasers has not yet proved to be particularly important. Developments in multiphoton ionisation of alkali atoms look very promising, since the atom can be pumped into a fully polarised excited state and then photoionised with a second circularly polarised laser beam. The electrons are then not only expected to be almost fully polarised, but also to have the least energy spread of any source of electrons, so that interesting experiments with low energy polarised monochromatic electrons should become possible. ☐

REVIEW ARTICLE

Intermediate filaments as mechanical integrators of cellular space

Elias Lazarides

Division of Biology, California Institute of Technology, Pasadena, California 91125

Five chemically distinct classes of intermediate filaments can be identified within higher eukaryotic cells. Each class is characteristic of a particular cell type. These filaments may function to integrate mechanically the various structures of the cytoplasmic space in a way that is tailored to the differentiated state of the cell.

FOR some years electron microscopy has identified a major filamentous system in the cytoplasm of higher eukaryotic cells that is distinct from actin filaments, microtubules and myosin filaments. As their characteristic diameter of 100 Å is between that of the smaller actin filaments (60 Å) and the larger microtubules (250 Å) and myosin filaments (150 Å), this new filamentous system has come to be known as the 'intermediate filaments'. Intermediate filaments were at first widely regarded as disaggregation products of either microtubules or myosin filaments and as a result they were neglected. But new biochemical and immunofluorescent techniques have recently established intermediate filaments as a distinct fibrous system composed of chemically heterogeneous subunits. The subunit structure defines five major classes of intermediate filaments that can be distinguished both biochemically and immunologically: (1) keratin (tono) filaments, found in epithelial cells and cells of epithelial origin; (2) desmin filaments, found predominantly in smooth, skeletal and cardiac muscle cells; (3) vimentin filaments, found in mesenchymal cells and cells of mesenchymal origin; (4) neurofilaments, found in neurones; and (5) glial filaments, found in all types of glial cells. It is common to find two of these classes co-existing in the same cell. This review highlights the most recent studies which have led to these conclusions and focuses on certain observations that shed light on the cytoplasmic function of these filaments. From these studies, it seems that intermediate filaments have a very important role in the mechanical integration of various cytoplasmic organelles.

Keratin filaments

Keratin filaments are perhaps the most atypical of all intermediate filament classes. Mammalian keratins are a group of intracellular α-fibrous proteins associated in a filamentous form (tonofilaments) with an approximate diameter of 80 Å. They are actively synthesised by the inner, living cell layers of the mammalian epidermis and represent its major differentiation product. Eventually, the keratins form the bulk of the outer, fully differentiated, dead, stratum corneum layer[1].

In addition to being the major differentiation product of epidermal cells, keratins are present in certain other stratified squamous epithelia[2,3], but they are absent from cells of mesenchymal origin (Table 1). Antibodies to the mammalian keratins have been used in immunofluorescent studies to identify many epithelial cells in culture or in tissue sections[4–7]. Generally, these antibodies show a wide cross-reactivity among species, indicating that different keratins are immunologically related. In cultured epithelial cells, the keratin filament bundles which react with the antibodies form an elaborate array throughout the cytoplasmic space (Fig. 1). Electron microscopy shows that bundles of keratin tonofilaments often terminate in membrane-bound desmosomes[4–7].

Keratins are insoluble in neutral aqueous buffers, but can be extracted in the form of a multichain unit[8,9] at low *p*H or by denaturing solvents (for example, 8 M urea). A reducing agent is also required for the efficient solubilisation of keratins from the terminally differentiated cells. Electrophoresis in denaturing gels separates keratin into a family of polypeptides with molecular weights (MW) ranging from 40,000 to 65,000 (refs 10–14 and refs therein). Keratins extracted in the presence of urea from the living cells of epidermis[11–13] or from cultured human keratinocytes[14] are composed of six to seven major polypeptides which have MWs of 47,000 to 58,000. Dialysis of the urea extracts against a dilute salt solution results in the spontaneous formation of filaments without any obvious requirement for a specific cofactor(s) such as divalent cations and nucleoside triphosphates. The reconstituted filaments show the same polypeptide composition, morphology, characteristic diameter of 80 Å and X-ray diffraction patterns as native filaments[10–14]. Extraction and reconstitution experiments suggest that most keratins of living cells exist in a reduced form that favours polymerisation and become increasingly cross-linked by intermolecular disulphide bonds as differentiation proceeds[12–14].

Most combinations of two or three purified keratin polypeptides polymerise *in vitro* into filaments of the same general structure as native keratin filaments. With two polypeptides, reconstitution is in the precise molar ratio of 1 : 2 whereas with three polypeptides equimolar reconstitution is the rule[12]. These ratios are maintained even in filaments polymerised from mixtures containing disproportionate amounts of polypeptides, indicative of a highly specific interaction between the various keratin polypeptides[12]. X-ray diffraction data had also indicated that native epidermal keratin filaments are composed of a fundamental three-chained structural unit[15–17]. As the keratins are composed of six or seven polypeptides, many triple-chained units of similar structure but of different polypeptide composition must be possible. Thus, several different triple-chained units may assemble to form a single filament[12]. If this is the case, then both the reconstituted and native filaments are likely to be heterogeneous with respect to polypeptide composition. Such filament heterogeneity may confer specificity to the cytoplasmic function of keratin filaments.

The biochemical relationship between individual keratins has been investigated by several groups[10–14,18]. Although the keratins of human epidermal cells grown in tissue culture are similar to those of stratum corneum of human epidermal callus with respect to their solubility properties, immunological reactivity and ability to assemble into 80-Å filaments *in vitro*, there are differences in the MWs of some of the proteins and the number of components[14,18]. In particular, the largest protein of stratum corneum (MW 63,000) is absent from the keratins of cultured human or mouse keratinocytes[14]. This high MW keratin seems to be characteristic of the stratum corneum. In another study, the keratins from two epidermal tissues of the same species,

bovine hoof and snout, were shown to be similar with respect to their MWs, amino acid compositions and percentage of helical structure[19]; however, one of the high MW (67,000) polypeptides from snout was absent from hoof keratin. In addition, the tryptic and cyanogen bromide peptides of total keratins from hoof and snout were distinctly different[19]. Thus, not only do differences exist in the keratins between different stages of epidermal cell differentiation, but also in keratins of different epidermal tissues of the same species. Furthermore, all of the keratins found in cellular extracts of cultured human epidermal cells are synthesised *in vitro* by distinct mRNA species isolated from these cells[20]. The kinetics of translation of these proteins is inconsistent with any type of precursor–product relationship within the keratin family or with the existence of precursors larger than the keratins[20]. These experiments have also clearly shown that epidermal keratins are a family of closely related but distinct proteins that are evolutionarily conserved.

Similar evidence for the existence of multiple genes was obtained first for the avian feather keratins[21,22], a family of proteins with MWs near 10,000 which assemble into 30-Å (tono) filaments and are thus quite different from epidermal keratins. By electrophoretic mobilities, amino acid composition and immunological criteria, the keratins of chicken feathers are distinct from those of scales. Differences exist as well between embryonic and adult tissues[21]. Nucleic acid hybridisation experiments have indicated that the number of genes for these low MW keratins may be 100 to 240 (ref. 22). All these results suggest that distinct sets of keratin genes are expressed during epithelial cell differentiation, in different developmental stages and in different epithelial tissues.

Desmin filaments and their role in the mechanical integration of myofibrils in muscle cells

It has been suspected that in muscle cells there is a cytoskeleton which holds the constituent myofibrils in place. The presence of structural elements transverse to a muscle fibre's long axis is suggested by the tendency for the Z disks, M lines and other sarcomeric units of neighbouring myofibrils to be in axial register across the fibre, thereby giving rise to the striking cross-striated appearance of the muscle cell[23]. Since the early days of light and electron microscopy of muscle, fibrous elements were observed to link myofibrils laterally at their Z, N and M lines and to link them to the surface membrane of the whole fibre[24–27], but only recently have they been characterised as intermediate filaments. The distribution of the filaments is characteristic of skeletal, cardiac or smooth muscle cells.

While intermediate filaments are present in both the embryonic and adult forms of all three muscle types [28–35], they are most abundant in adult smooth muscle. Here, these filaments form an interconnected network that links cytoplasmic dense bodies with membrane-bound dense plaques[30,34,35]. Morphological studies have shown that actin filaments are also inserted into these electron-dense structures[29], which can be shown to contain α-actinin and tropomyosin using immunocytochemical techniques[36]. Thus, smooth muscle dense bodies appear analogous to striated muscle Z lines.

Extractions of smooth muscle cells with high salt buffers renders contracile actin and myosin filaments soluble, leaving behind a cytoskeleton composed predominantly of intermediate filaments still attached to dense bodies[34,35]. Electrophoretic analysis indicates that this cytoskeleton consists of two major proteins: actin; and a 50,000–55,000-MW protein which we have named desmin (from the Greek noun δεσμός = link, bond)[37,38]. An identical protein has been isolated by Small and Sobieszek from mammalian smooth muscle and has been referred to as skeletin[39]. On dialysis or neutralisation, purified desmin polymerises into into a gel-like network of filaments. Reconstituted desmin filament have the same average diameter (100 Å) as smooth muscle intermediate filaments[38,39]. A small amount of actin appears to be stably associated with desmin[38,40]. The actin bound to desmin is likely to be in a conformation different from thin filament actin. It is not yet known if the interaction of desmin with actin is restricted *in vivo* in its extent and spatial location, but such an interaction might well occur at cytoplasmic or membrane-bound dense bodies, where actin and desmin filaments exist in very close proximity.

The small size of smooth muscle cells and their complicated morphology make *in situ* studies difficult, and for this reason we have used skeletal muscle for our cytological investigations of desmin. Although common in embryonic striated muscle, intermediate filaments become progressively less visible as the sarcomeres condense and become laterally registered. Intermediate filaments are rarely seen in adult muscle[41], but substantial amounts of desmin can be detected in adult striated muscle by electrophoretic and immunological methods[37,42–44]. Using immunofluorescence on longitudinal sections of myofibrils, desmin was shown to be localised in both skeletal and cardiac muscle Z lines and in regions of cell–cell juncture and apposition of the Z line with the plasma membrane (cardiac intercalated disks)[37,42,44,45]. Desmin is thus the third protein, in addition to α-actinin and actin, to be localised at the Z line using immunocytochemical techniques[45–47]. To obtain information on the spatial relationships of these three proteins within the plane of a single Z disk, it was necessary to develop a method which allowed a face-on view of Z disks by light microscopy as well as by electron microscopy. Normally when a muscle fibre is sheared, it is cleaved lengthwise, between laterally associated Z disks, to produce myofibrils, but we discovered that if most of the myosin and actin are first extracted from the fibre with high salt, the fibre's longitudinal strength is reduced and subsequent blending shears the fibre transversely between Z planes, producing honeycomb-like sheets of Z disks[48]. The generation of sheets of interconnected Z disks lends support to the idea that the Z disks within a Z plane are actually connected to one another. Electrophoretic analysis indicates that these Z planes are composed predominantly of actin and desmin (as is the case with smooth muscle dense body cytoskeletons).

Indirect immunofluorescence performed on a single Z disk sheet reveals that desmin is present at the periphery of each Z disk, forming an interconnecting network across the fibre (Fig. 2*a*). α-Actinin is localised within each disk, giving a face-on fluorescence pattern that is complementary to that of desmin (Fig. 2*b*). Actin is present throughout the Z plane, apparently co-existing with both desmin and α-actinin[48]. Thus, the Z disk is composed of two molecular domains, a peripheral one which contains at least desmin and actin, and a central one which contains at least α-actinin and actin. Do these two domains assemble at different times during myogenesis? In the early stages of myogenesis, electron microscopy[31,32,41] and immunofluorescence with desmin-specific antibodies[49] reveal that numerous desmin filaments exist scattered in the cytoplasm, not associated with the newly forming Z disks and sarcomeres. During this time the filaments can be induced to aggregate into bundles by exposing the cells to colcemid (Fig. 3)[31,42,49,50]. Later in development, desmin and intermediate filaments begin to associate with and encircle the Z disks[49] and become resistant to aggregation by colcemid[49]. Therefore, desmin and other Z disk components may undergo a 'molecular maturation' during myogenesis which allows their association.

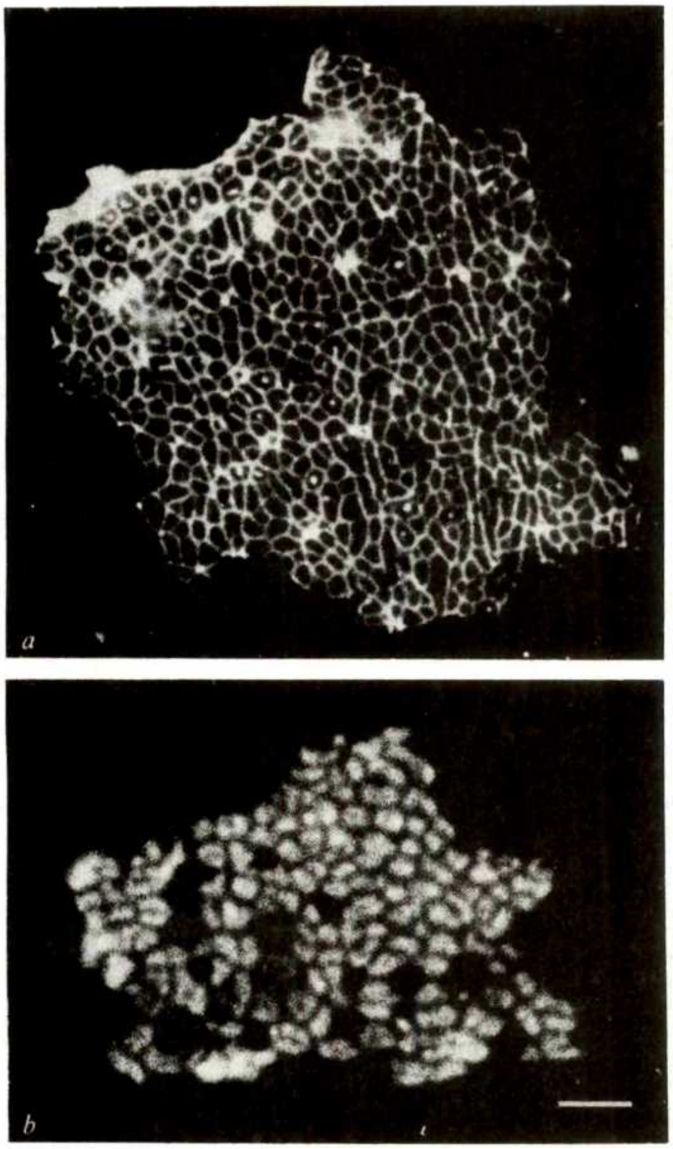

Fig. 2 *a*, The distribution of desmin at the periphery of Z disks in isolated Z disk sheets from chicken skeletal muscle. Indirect immunofluorescence using antibodies to chicken smooth muscle desmin. Vimentin shows the same distribution as desmin in these sheets (see ref. 49). *b*, The distribution of α-actinin in the interior of Z disks in isolated Z disk sheets from chicken skeletal muscle. Indirect immunofluorescence using antibodies to chicken muscle α-actinin. Scale bar, 2.5 μm.

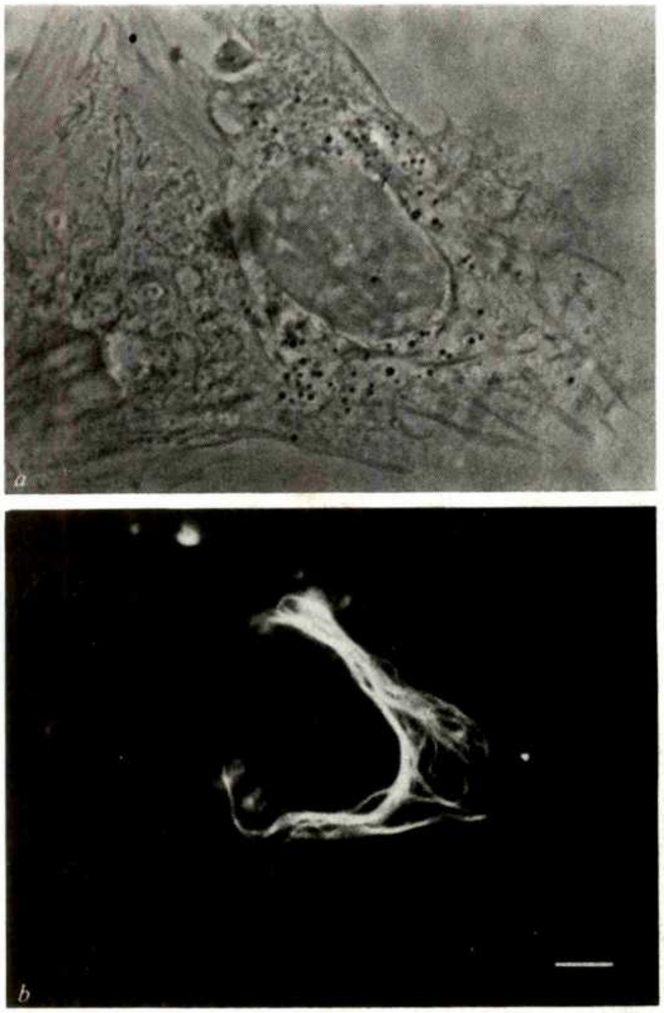

Fig. 3 The perinuclear aggregation of intermediate filaments in primary chick embryonic cardiac cells exposed to colcemid. *a*, Phase contrast image; *b*, fluorescence image. Indirect immunofluorescence using antibodies to chicken smooth muscle desmin. Similar images are obtained using antibodies to vimentin (see text). Scale bar, 10 μm.

In most types of skeletal muscle, the Z disks are encircled by the electrically excitable transverse-tubular (T) membrane. This membranous system is an extension of the plasma membrane and forms junctions (triads) with the terminal cisternae of the calcium-sequestering sarcoplasmic reticulum (SR) membrane which surrounds the rest of the myofibril[51–56]. Electron microscopy of isolated Z disk sheets (Z planes) shows membranous elements, presumably of T-system and SR origin, surrounding the individual Z disks[48]. Those same regions react strongly when the sheets are exposed to specific probes that fluoresce only in a hydrophobic environment[57]. The distribution of the membranous material in Z planes is coincident with that of desmin and complementary to that of α-actinin[57].

Linkages between adjacent myofibrils may not be restricted to the Z disk. Electron microscopy of actomyosin-depleted myofibrils demonstrates that fibrous linkages exist between adjacent myofibrils also at the M and N lines[48]. In some types of muscle the triadic junctions of the T-system are positioned at the sites of overlap of the thin and thick filaments (A–I junction)[56]; similar fibrous linkages may be involved in anchoring the triads to the periphery of the myofibril at these sites. The molecular composition of these links is presently unknown.

One seemingly puzzling observation is that in adult skeletal muscle fibres intermediate filaments are only rarely seen by conventional electron microscopic techniques. However, in certain cases, bundles of intermediate filaments have been observed surrounding skeletal muscle Z disks and extending laterally between them[41,56,58]. The presence of high concentrations of membranous material in the intermyofibrillar space may frequently obscure the presence of intermediate filament connections between adjacent Z disks, M lines and N lines[59]. Similarly, in cardiac muscle, bundles of intermediate filaments appear to surround Z disks and to connect them to the triad junctions irrespective of the position of the triad within the sarcomere (that is, at the Z line or A–I junction)[60–64]. Occasionally these filaments extend from the Z disks to the nuclear and plasma membranes[61–63]. Intermediate filaments are especially prominent in hypertrophied myocardial cells[61] or in cardiac muscle cells of animals treated with anabolic steroid hormones[64].

On the basis of these observations, we have proposed the following functions of desmin and desmin filaments in muscle cells[37,40,48,65], a schematic representation of which is shown in Fig. 4. First, desmin may mechanically integrate all contractile actions of a muscle fibre by linking individual myofibrils laterally at their Z disks and by linking Z disks to the plasma membrane and to other cytoplasmic membranous organelles. This arrangement will also ensure the maintenance of the proper alignment of cellular structures during the contraction–relaxation cycle of muscle. During the biogenesis and assembly of myofibrils, desmin may have an important role in the generation of the striated appearance of muscle by bringing the Z disks into lateral register. Second, desmin may function in the biogenesis of the T–SR membrane system. Some mechanism is required to direct the deposition of this membrane system to the periphery of the Z disk. A protein with both membrane and Z disk affinities, like desmin, could be vital in this process. As desmin binds to actin, desmin may also mediate the attachment of actin at additional membrane sites such as cardiac intercalated disks and smooth muscle dense bodies. We can further hypothesise that this transverse mechanical integrating system of desmin filaments may be an essential feature of all types of muscle regardless of their position in the evolutionary scale[44]. The proposed function of desmin indeed seems to justify its name and provides the first well documented cytoskeletal function for intermediate filaments.

Vimentin filaments

A variety of cells of mesenchymal or non-mesenchymal origin contain vimentin filaments (see Table 1), so called because immunofluorescence studies with antibodies to the major subunit of these filaments reveal a wavy (Latin *vimentus*) cytoplasmic filamentous system (Fig. 5)[6,73].

Vimentin was first characterised as a 52,000-MW, major subunit of intermediate filaments in chick embryo fibroblasts[66]. The wide cross-reactivity of vimentin antibodies with cells of mammalian, avian or amphibian origin indicates that this protein is conserved in evolution[6,67–69].

Table 1 Presence of intermediate filament subunits in different cell types

Cell type	Vimentin (MW 52,000)	Desmin (MW 50,000)	Keratins (MW 40,000–65,000)	Glial filaments (GFA) (MW 51,000)	Neurofilaments (MW 200,000, 150,000, 68,000)

Compiled from data in refs 3, 4, 5–7, 37, 38, 42–44, 67–69, 73, 86, 95–102, 108, 109. ND, not determined.

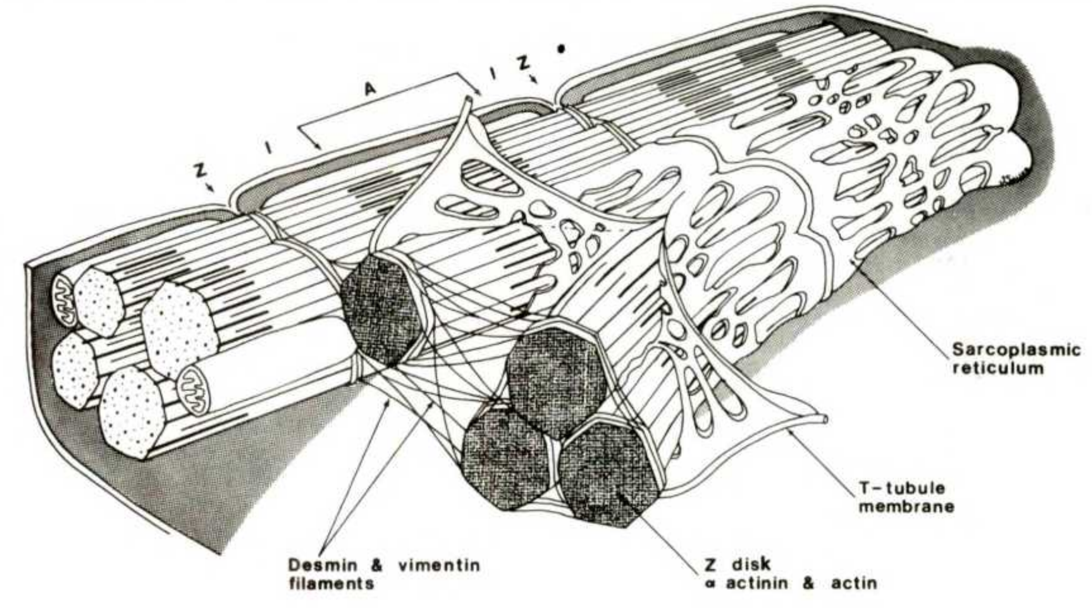

Fig. 4 Schematic representation of the distribution of desmin, vimentin, α-actinin, actin and membranous organelles in relationship to chicken skeletal myofibril Z disks.

One of the most interesting and characteristic properties of vimentin-containing intermediate filaments is their aggregation into perinuclear filamentous bundles in the form of a cap or a ring in cells exposed to colcemid[70–73], a finding which originally prompted the erroneous belief that these filaments were degradation products of microtubules. Similar structures exist transiently during normal cell adhesion and spreading onto a substrate[74,75] or in non-motile tumour cells[76]. Isolated filament caps contain two predominant polypeptides in approximately equimolar amounts, one with a MW of 52,000–55,000 which corresponds to vimentin in other cell types, and the other with a MW of 50,000–54,000 which, as discussed below, corresponds to muscle desmin. Vimentin and desmin can be purified from the birefringent caps by repeated cycles of disassembly–reassembly, induced by lowering and raising the ionic strength of the extracting solutions[75,77]. Reassembled filaments have an average diameter of 100 Å; it is not known whether vimentin and desmin copolymerise into a single filament or whether they polymerise into distinct filaments with common properties. Vimentin has now been identified in a variety of cell types, quite frequently in co-existence with the major subunit of some of the other classes of intermediate filaments (see below).

Vimentin filaments are very insoluble, suggesting that they have a structural function in the cytoplasm. They frequently terminate at both the nuclear membrane and the adhesion plaques of detergent-extracted cytoskeletons prepared from cultured fibroblasts[78,79] or nucleated chicken red blood cells[80]. In normal conditions (in the absence of colcemid), there is always a certain perinuclear concentration of 100-Å filaments in the cell lines studied[79]. Enucleation of cells by cytochalasin B produces karyoplasts surrounded by intermediate filaments and cytoplasts in which intermediate filaments remain situated in the central region of the cytoplasm[79]. Together these results strongly suggest that vimentin is tightly associated with the cell nucleus, possibily providing it with mechanical support and constraining it in a specific place in the cell[78–80]. In this respect, several other observations have also been made of the association of intermediate filaments with centrioles *in situ*[75,81].

The fate of vimentin filaments during the cell cycle appears to vary from one cell type to another. In BHK-21 cells the filaments disaggregate during prometaphase and reappear as filamentous caps in the perinuclear area during the spreading of the two daughter cells[75]. However, in most other cell types (NIL-8, endothelial cells), the filaments appear to persist in a polymerised form throughout mitosis[72,73,82]. In vascular endothelial cells, the interphase cells contain a ring of intermediate filaments that encircles the nucleus and is maintained in a plane parallel to the substrate[72,82]. During prophase and metaphase the cells round up and the filament ring becomes wavy, although it still exists as a closed structure. During anaphase the ring elongates into a rectangle that contains the spindle apparatus and chromosomes. In late telophase, cytokinesis cleaves the filaments into crescents at the site of the contractile ring, which then close into rings in the daughter cells[82] (see Fig. 6).

Neurofilaments and glial filaments

Neurofilaments (average diameter 100 Å) and microtubules (250 Å diameter) comprise the main structural elements of neuronal axons, dendrites and perikarya. The neurofilaments can be either randomly or uniformly dispersed and appear to be linked to each other through wispy sidearm appendages. Glial filaments are found randomly dispersed in the cytoplasm of astrocytes and other types of glial cells; in contrast to the neurofilaments, glial filaments are more closely packed (average diameter 80 Å), are less parallel in their orientation and lack sidearm appendages[83].

There has been prolonged controversy and confusion over the subunit composition of neurofilaments and glial filaments. The first intact intermediate filaments to be isolated[84] were derived from myelinated nerve fibres and were therefore assumed to be characteristic neurofilaments with a 51,000-MW protein derived therefrom being the neurofilament protein. This assumption was erroneous. It has since been clearly demonstrated that these filaments were predominantly glial filaments with a 51,000-MW glial fibrillary acidic (GFA) protein as their major subunit.

When neurofilaments are purified from the peripheral nervous system (PNS), which is relatively free of glial cells, no protein with a MW of 51,000 is detected[85,86]. Instead, rat peripheral nerve, rat spinal cord and rabbit intradural spinal nerve roots[85–88] each contain three major polypeptides with MWs of 200,000, 150,000 and 68,000. In contrast, squid neurofilaments are composed of only two major polypeptides with MWs of 200,000 and 60,000 (refs 89–91), while those from the giant axon of the marine worm, *Myxicola infudibulus*, are composed of two polypeptides with MWs of 160,000 and 150,000 (refs 89, 92). In spite of these differences, however, one of the characteristic properties of both vertebrate and invertebrate neurofilaments is their extreme susceptibility to proteolysis in the presence of Ca^{2+} ions[92,93].

The biochemical evidence distinguishing neurofilaments from glial filaments has been supported by immunological studies with antibodies prepared with and specific for the purified subunit proteins of neurofilaments and glial filaments. Antibodies raised to the 68,000-MW components of mammalian peripheral nerve react in immunofluorescence with axons and

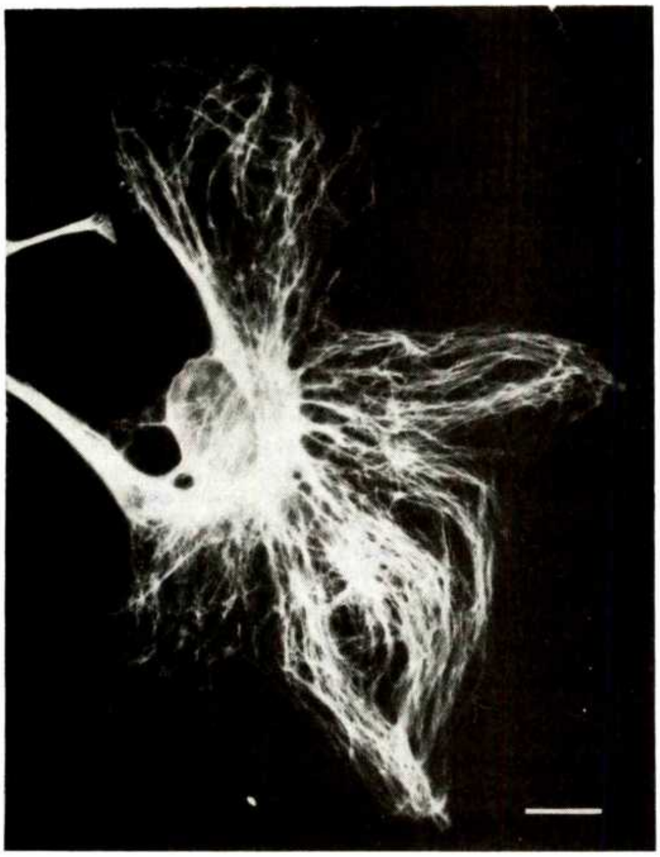

Fig. 5 The distribution of intermediate filaments in a normal chick embryonic fibroblast using antibodies to chicken vimentin in indirect immunofluorescence (courtesy of B. L. Granger). Scale bar, 10 μm.

neurones throughout mammalian PNS and central nervous system (CNS) but do not react with glial cells[86,94,95]. Similarly, antibodies to GFA react in immunofluorescence only with glial cells or cells of glial origin and do not react with neurones or their processes[86,96,97] (for a review on GFA and its properties see ref. 98). Antibodies to GFA do not react with muscle cells, myofibrils, or fibroblasts, indicating it is immunologically distinguishable from vimentin and desmin[44]. Conclusive demonstration that GFA is the major component of glial filaments stems from the observations that (1) GFA is the major component of purified glial filaments[99]; (2) purified GFA will assemble *in vitro* into filaments with an average diameter of 100 Å (ref. 98); and (3) antibodies to GFA will react with glial 100-Å filaments *in situ* using the immunoperoxidase method[96].

While the function of glial filaments is presently undetermined, neurofilaments appear to function as a three-dimensional structural lattice that provides tensile strength to the axons. This idea stems from the observation that the extruded axoplasm from *Myxicola* is a highly structured gel consisting almost exclusively of neurofilaments[91,92]. Exposure of this gel to Ca^{2+} results in the degradation of neurofilaments and the dissolution of the gel.

Co-existence of different intermediate filament subunits in the same cell

A number of cells have recently been shown to possess the subunits of at least two distinct intermediate filament types, sometimes in clearly distinguishable filamentous systems. For example, PtK_2 and HeLa cells have abundant keratin filaments in their cytoplasm and contain vimentin in the perinuclear aggregates of intermediate filaments experimentally induced by colcemid[6,7]. Both polypeptides can also be demonstrated in these cells by electrophoretic analysis of their filamentous detergent insoluble cytoskeletons[6,7].

Similarly, two-dimensional electrophoresis of the cytoskeletons from fibroblast-free cultures of chicken embryonic muscle, chicken embryo fibroblasts, 3T3 cells and BHK-21 cells shows that all these contain not only vimentin but also a second polypeptide which is highly homologous to muscle desmin[100,101] and can be detected by immunofluorescence in colcemid-induced perinuclear rings of intermediate filaments[100]. In skeletal myotubes and isolated myofibrils, the distribution of desmin and vimentin coincides[49].

Recent immunofluorescent experiments also suggest that glial cells (glioma cells and astrocytes) contain vimentin in addition to the glial-specific filament subunit (GFA)[6,68,69,102]. In cultured astrocytes, vimentin and glial filaments can be distinguished by their characteristic immunofluorescence patterns. The possible presence of vimentin in purified glial filaments and the natural occurrence of autoantibodies to vimentin may explain the wide cross-reactivity observed in earlier studies with antibodies to GFA[103].

These observations demonstrate that desmin and vimentin can co-exist in muscle and non-muscle cells; similarly, vimentin and certain keratins can co-exist in some epithelial cell types, and vimentin and GFA can co-exist in glial cells. While vimentin and keratin filaments can be distinguished easily by electron microscopy and their responses to colcemid, this is not the case with vimentin and desmin filaments. Both desmin and vimentin filaments appear morphologically (that is, by transmission electron microscopy) very similar and aggregate into perinuclear rings in cells exposed to colcemid (see Fig. 2*b*). As desmin and vimentin from BHK-21 cells co-purify through cycles of polymerisation–depolymerisation (see above), it will be intriguing to find out whether the two polypeptides can co-polymerise into one and the same filament, as is the case with the keratins, or whether they polymerise into distinct filaments. Immunoelectron microscopy with desmin and vimentin antibodies should answer these questions. At present, the function of desmin in non-muscle cells and of vimentin in muscle cells is unknown, but by analogy to muscle cells, desmin may be involved in the adhesion of actin filaments to the plasma membrane.

Phosphorylation of intermediate filament subunits

All intermediate filament subunits examined to date seem to be phosphorylated *in vivo* and can be phosphorylated *in vitro*. For example, phosphorylation of the 200,000 but not the 60,000-MW polypeptide from squid axoplasm occurs after intracellular injection of $[\gamma\text{-}^{32}P]ATP$ into giant axons or addition of $[\gamma\text{-}^{32}P]ATP$ to extruded axoplasm[90]. In contrast, both *Myxicola* neurofilament polypeptides are phosphorylated *in vivo*, probably by a soluble kinase which is independent of Ca^{2+} cyclic AMP or cyclic GMP for its activity[104]. A portion of this activity remains associated with neurofilaments even after extensive purification of the filaments[104]. Similarly, all three polypeptides of the mammalian neurofilament triplet[104] are phosphorylated.

A non-phosphorylated and several phosphorylated variants of desmin and vimentin are present in assembled structures (Z disks, dense body attached and cytoplasmic intermediate filaments) in muscle[105] and non-muscle cells[100,105,106] while some of the keratin polypeptides are also multiply phosphorylated[14].

Three major activities can be identified in muscle extracts that phosphorylate purified smooth muscle desmin or desmin and vimentin in fibroblastic filamentous cytoskeletons. Two of the activities co-purify with the muscle cyclic AMP-dependent protein kinases and are inhibited by the cyclic AMP-dependent protein kinase inhibitor protein[107]. The other activity seems to be cyclic AMP independent[107].

The role of phosphorylation in the regulation of assembly or any other function of intermediate filaments is at present unknown. However, as assembled intermediate filaments are always phosphorylated, phosphorylation may be involved in determining the state of polymerisation or aggregation of these structures.

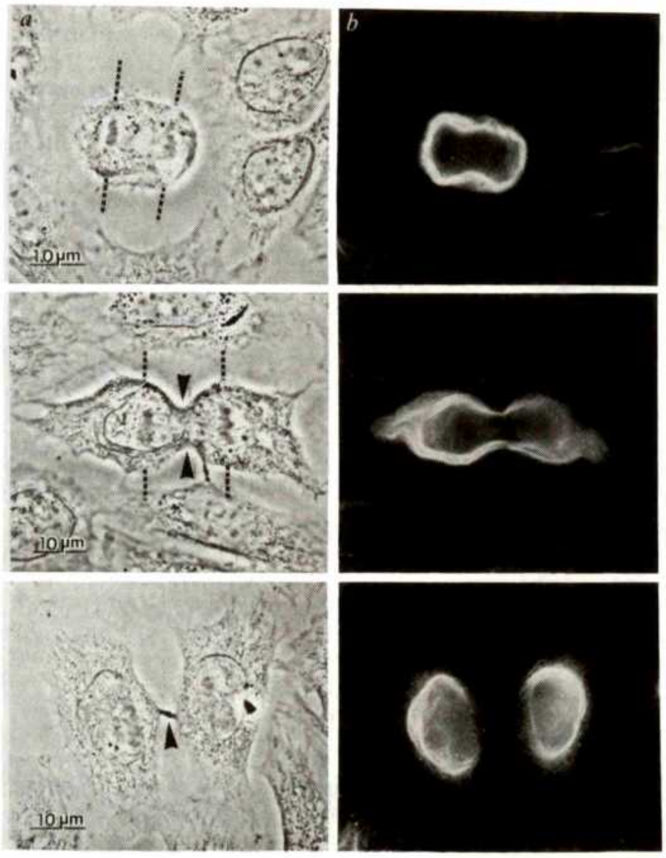

Fig. 6 Endothelial cells during mitosis. Phase (*a*) and immunofluorescent (*b*) micrographs using antibodies to vimentin. Scale bars, 10 μm. Top, anaphase. The dotted lines indicate the position of the chromosomes. Middle, telophase. The contractile ring, indicated by arrowheads in the phase micrograph, begins to pinch the intermediate filaments observed by immunofluorescence. Bottom, late telophase. Cytokinesis has now completely cleaved the ring into two symmetrical crescents that enter the daughter cells. The arrow points to the midbody (from S. Blose, ref. 82).

Prospects for the future

Now that the biochemical and immunological taxonomy of the various intermediate filaments is nearly complete, certain intriguing biological questions arise. The majority of cytoplasmic microtubules and actin filaments emanate from or terminate at one or more nucleation or organisation sites. No such sites have yet been identified for intermediate filaments, but they would have to exist to provide directionality of growth and three-dimensional organisation to these filaments. Keratin filaments are frequently found in association with desmosomes, desmin filaments with substructures of intercalated disks and vimentin filaments with the nuclear membrane; perhaps these structures can function as nucleation sites for the growth of the respective filaments. In general, intermediate filaments are insoluble in physiological buffers, but highly susceptible to proteolysis, especially in the presence of Ca^{2+}. As these filaments exist mainly in the cytoplasm in a full polymeric state, perhaps their disassembly is regulated by a proteolytic mechanism rather than by a polymerisation–depolymerisation equilibrium as is the case with microtubules. Such a proteolytic mechanism would have an important regulatory role in shape changes that occur during locomotion and cell division.

The co-existence of desmin and vimentin is interesting and it will be important to determine whether the two proteins copolymerise into one and the same filament or co-exist in distinct independent filaments. Skeletal muscle differentiation emerges as a very interesting system to elucidate the proposed function of desmin filaments, the molecular details of the interaction of these filaments with actin and the various types of membranous organelles and the molecular events that lead to their ultimate association with the Z disks. The high degree of keratin polymorphism and the changes in their expression during epidermal differentiation make epidermal differentiation *in vitro* an attractive model system to study the developmental expression of the keratin genes. Finally, although intermediate filaments can be distinguished by immunological methods and peptide mapping, they share a number of properties. To reconcile their morphological similarity and chemical heterogeneity, it is possible to imagine that the subunits of the intermediate filaments are analogous to IgG molecules, namely, that they are composed of a constant and a variable domain. The constant domain might be responsible for the conserved polymerisation of the protein subunits into filaments with an average diameter of 100 Å and their aggregation into filamentous bundles in cells exposed to colcemid. The variable domain might confer on the molecule functional specificity for the cell of which it is a part. Amino acid sequencing data will reveal the validity of this proposition.

Intermediate filaments have emerged as a polymorphic class of cytoplasmic filaments distinct from microtubules and actin filaments. All their biochemical and morphological properties so far indicate that they are involved in mechanically integrating the various components of the cytoplasmic space. As such they should be capable of multiple interactions with cytoplasmic structures, might be expected to have a crucial role in regulation of cell shape and may be influenced by the metabolic state and response to injury or malfunction of any cell in which they are contained.

I thank Dr C. M. O'Connor, B. L. Granger and D. L. Gard for their comments on the manuscript and J. Sauer for drawing Fig. 4. This work was supported by grants from the NIH (GM-06965) and the Muscular Dystrophy Association of America.

^{187}Re–^{187}Os systematics in meteorites: early chronology of the Solar System and age of the Galaxy

Jean-Marc Luck, Jean-Louis Birck & Claude-Jean Allegre

Laboratoire de Géochimie et Cosmochimie LA 196, Institut de Physique du Globe et Département des Sciences de la Terre,
Université Pierre et Marie Curie, Paris VI et VII, 4 Place Jussieu, 75230 Paris Cedex 05, France

Using isotope dilution mass spectrometry, we have determined the $^{187}Re/^{186}Os$, $^{187}Os/^{186}Os$ ratios of five iron meteorites of various groups, and one ordinary chondrite. These results show that iron meteorites and ordinary chondrites were formed within a short time. We determine the ^{187}Re decay constant as $1.62 \pm 0.03\ 10^{-11}\ yr^{-1}$ and the $^{187}Os/^{186}Os$ isotopic ratio at the origin of the Solar System as 0.805 ± 0.011. These values are used to compute limits for the age of the Galaxy between 13,300 and 22,400 Myr.

^{187}Re is one of the long-lived radioactive nuclides with a decay constant (λ) of the order of 10^{-11} yr^{-1}. It produces ^{187}Os by (β^-) decay. Therefore, like ^{87}Rb–^{87}Sr or ^{40}K–^{40}Ar, the ^{187}Re–^{187}Os system is a potential cosmochronometer[1]. Some peculiar properties of the Re–Os system make it particularly attractive for dating the early formation of the Solar System and for estimating the age of the Galaxy.

(1) Re and Os are refractory siderophile elements that concentrate in the metal and sulphide phases of meteorites[2]. These phases are the dominant material not only in iron meteorites, but also in pallasites and mesosiderites. With regard to ordinary and enstatite chondrites, Re and Os are also mainly contained in the metal phase. Thus Re–Os measurements on this metal phase will give the absolute age of different types of meteorites.

For iron meteorites Re/Os fractionation, being presumably related to the fractional crystallisation of metal in the core of their parent body[3], the eventual isochron is expected to date the formation of irons, that is, the differentiation of parent bodies.

In this way, it would be possible to propose a relative chronology of the early history of the Solar System by comparing the respective ages of, for example, irons and chondrites. Note that in the case of irons this chronometer will lead to an accurate dating, a controversial subject because no other reliable absolute chronometer can be applied to the metal itself: the Rb/Sr is very sensitive to secondary perturbation events[4], Pb isotopic composition is primordial in iron meteorites[5], and K–Ar has a limited use because of spallation phenomena.

(2) ^{187}Re has a half life of the order of magnitude of the age of the Galaxy[6,7] and is, therefore, potentially a good way of obtaining precise estimates for this age. If ^{187}Re is produced by (r) processes, ^{187}Os and ^{186}Os are produced by (s) processes only and hence their production rates are not submitted to the uncertainty of the (r) process.

Besides these advantages, the ^{187}Re–^{187}Os system contains some basic difficulties: first, we do not know the decay constant exactly

0028-0836/80/030256—04$01.00

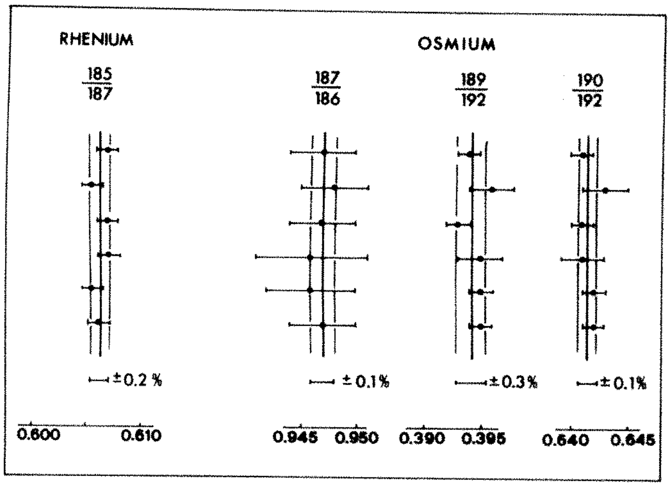

Fig. 1 Reproducibility of ion-probe measurements of standard isotopic compositions of Re and Os.

because its direct measurement by counting methods in the laboratory is very difficult[8]; second, the content of Re and Os in meteorites is quite low (3–0.3 p.p.m.) and the precise isotopic analysis of osmium isotopes is quite difficult at this level.

These difficulties explain why the only serious attempt to use the ^{187}Re–^{187}Os chronometer in cosmochronology was done by Herr *et al.*[1] and Hirt *et al.*[9] in the early sixties. The German–Swiss group has approached the above difficulties by determining the rhenium decay constant using terrestial molybdenites the age of which was approximately known[10]. They obtained $1.61 \pm 0.19 \times 10^{-11}$ yr^{-1}. To overcome the second problem they used gas source mass spectrometry but their technique was neither very sensitive nor precise. Using their previously determined decay constant, they obtain for iron meteorite samples from several groups an age of 4,000 Myr.

We have used a more refined technique for Re and Os measurements, considered a new set of iron meteorites plus one chondrite, and recalculated the age of the Galaxy.

Experimental technique

We have used, both for Re and Os, isotope dilution mass spectrometry, using ^{185}Re and ^{190}Os spikes prepared by Oak Ridge National Laboratories. After dissolution and spiking Re and Os are separated chemically, then loaded on an aluminium disk and run separately in an ion-sputtering mass spectrometer. The separation between Os and Re is absolutely crucial because they interfere at mass 187—the mass of interest.

Chemistry: The details of the technique will be published elsewhere and only the principles are described here.

Metal phases are dissolved in 6M H_2SO_4 and at the same time ^{185}Re and ^{190}Os spikes are added. Oxidation is carried out through an excess of CrO_3 and osmium is distilled at 110 °C as OsO_4 into a cooled water trap. After transforming the oxide to bromide then to chloride, Os is loaded on an anion-exchange column for purification. It is eluted with 4M HNO_3 and then loaded on a 99.99% pure aluminium disk.

Re is extracted from the distillation residue by tribenzylamine in chloroform and then back extracted with ammonia into aqueous solution. It is loaded on an anion-exchange column, eluted with 8M HNO_3 and then loaded on a pure aluminium disk.

Mass spectrometry: The Cameca SMI300 ion probe was used as a sputtering mass spectrometer. The sputtering is done by a negative oxygen ion beam. The target is the Os or Re deposit on the aluminium disk. The machine which was largely modified for our experiments has been described elsewhere[11]. It is equipped with an energy filtering system through an electrostatic analyser nd a programmable magnetic field and digital output. Energy iltering eliminates most of the possible interfering species ncluding hydrocarbons.

Performances: The total blanks of our chemistry are: for Re < 3ng; for Os < 5ng. At such a low level the measurements are inprecise due to small interferences; we have, therefore, only estimated the possible upper limits. In fact, blanks are probably much lower. The reproducibility of isotopic ratio measurements in the mass spectrometer is ±0.2% for Re, ±0.1% for Os. The standard runs are illustrated in Fig. 1. A duplicate analysis has been done on the iron meteorite Tlacopetec to estimate whether isotope dilution was achieved:

Experiment 1 Re = 3.69 ± 0.03 p.p.m.
Os = 57.8 ± 0.3 p.p.m.
Experiment 2 Re = 3.29 ± 0.02 p.p.m.
Os = 57.7 ± 0.8 p.p.m.

These results show an extremely good reproducibility.

Meteorite chronology

As established by Hirt *et al.*[10] we can write the chronometric equation for a closed system using ^{186}Os as reference isotope.

$$({}^{187}\mathrm{Os}/{}^{186}\mathrm{Os})_{\mathrm{Today}} = ({}^{187}\mathrm{Os}/{}^{186}\mathrm{Os})_{T_0} + ({}^{187}\mathrm{Re}/{}^{186}\mathrm{Os})_{\mathrm{Today}}(e^{\lambda T_0} - 1)$$

where T_0 is the age at the closure of the system.

This equation is then used to compare ^{187}Os/^{186}Os with ^{187}Re/^{186}Os to determine the age of the system, the initial isotopic ratio of osmium, and at the same time to check if the subsystems are cogenetic and closed. We have thus analysed several iron meteorites of different classes: Canyon Diablo (IB), Coahuila (IIA), Henbury (IIIA), Casas Grandes (IIIA), Tlacotpec (IVB) and one ordinary chondrite, St Séverin (LL6). For each meteorite the iron part has been taken (separated in the case of St Séverin) and treated as described above. The results, given in Table 1 and Fig. 2, show a wide range of Re/Os values.

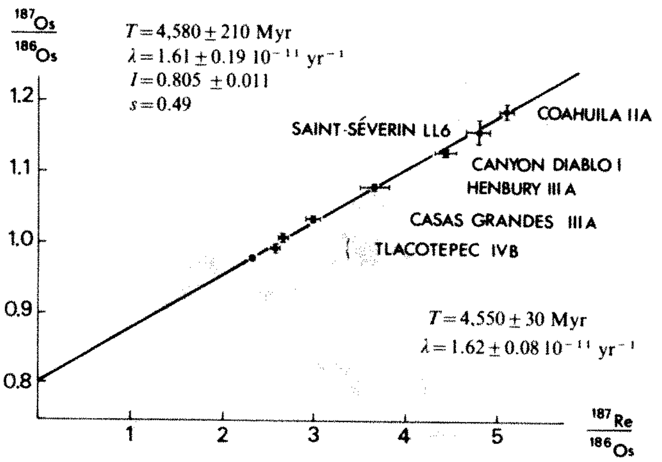

Fig. 2 ^{187}Re–^{187}Os evolution diagrams for five different iron meteorites from four different groups and one chondrite. *s* is the reduced χ^2 value and indicates the excellent fit to a straight line.

From both our isotopic measurements and from expected ^{187}Os/^{186}Os ratios for irons of various classes[2], it seems that the Re/Os ratio and, hence the radiogenicity of osmium, could depend on the class to which the iron belongs. That is, in general, meteorites from class I are expected to be more radiogenic than those from class IIIA, and less than that from class IIA. This slight trend could be related to the oxidation state of irons. However, the same data do not presently suggest any trend within a given group. In this case, the Re and Os fractionation might involve another factor besides the degree of fractional crystallisation of the metal phase. More measurements are needed to confirm these results.

Regarding the measurements made on the iron meteorites, all points fall remarkably on a single line defining an extremely good isochron ($s = 0.49$). The slope is 0.0765 ± 0.0035 and the initial ratio $^{187}Os/^{186}Os = 0.805 \pm 0.011$ (2σ errors). These two results differ substantially from the results of Hirt *et al.*[9] for the slope, as well as for the initial ratio and the precision (respectively 0.066 ± 0.013 and 0.83 ± 0.06). However, this difference is the normal difference which can be expected from almost 20 years of analytical progresses into the field: note that all our results are within the error limits given by the German–Swiss group. Using the decay constant $\lambda_{Re} = 1.61 \times 10^{-11}\ yr^{-1}$, we obtain an age of 4,580 ± 210 Myr.

Several conclusions can be drawn from these results.

First, within the accuracy of our measurements, the iron meteorites of several groups were formed with a short time interval with ordinary chondrites. Such an unequivocal result has not been clearly established before, except by I–Xe chronology[12,13]. The Rb–Sr approach of the Caltech group gave various ages from 4,700 to 3,800 Myr and no clear answer to this question[14]. However, all the precedent results dated the silicate inclusions, not the iron itself. Our results show that if iron meteorites come from differentiated bodies, such a differentiation occurred within a period of about 400 Myr in their respective parent bodies.

Second, the time interval between these events and the well determined formation of ordinary chondrites is very short—say <200 Myr; this value is obtained from the extreme ages for St Séverin (error limits) compared with the 4,580 Myr age for iron meteorites. Indeed as most, if not all, of Re and Os from chondrites is contained in their metallic part[15], the determination for Saint Séverin can be considered as that for the whole rock of this unperturbed ancient meteorite[16]. In other words, the differentiation of planetary bodies is a very early event in the Solar System. Such an early differentiation is consistent with the existence of early magmatic activity in the Solar System as determined on the Juvinas basaltic achondrite[17].

From our results we can deduce a decay constant for the ^{187}Re. The recent results from our group clearly establish the age of formation of basaltic achondrites[17,18], H chondrites[19], enstatite chondrites[20], and LL chondrites[16,19] both by Rb–Sr and U–Pb methods[21] in the range of 4,550 ± 30 Myr. Such results are also in good agreement with the data obtained by Turner *et al.*[22] using the ^{39}Ar–^{40}Ar method, and by Lugmair using the Sm–Nd chronometer[28]. Taking the age as 4,550 ± 30 Myr, we obtain $\lambda_{Re} = 1.62 \pm 0.08\ 10^{-11}\ yr^{-1}$. Note that such a value is extremely close to the previous value of $1.61\ 10^{-11}\ yr^{-1}$ determined by Hirt *et al.*[10] on terrestial molybdenite samples. We stress again the remarkable results obtained by these authors 20 years ago.

Age of the Galaxy

We will use the values of λ_{Re} and ($^{187}Os/^{186}Os$) initial ratio to determine the so-called age of the Galaxy following at first an early approach by Clayton[6].

^{186}Os and ^{187}Os isotopes are created by (s) nucleosynthetic processes. In addition, ^{187}Os contains a radiogenic contribution from ^{187}Re. On the other hand, ^{187}Re is created by (r) process. Therefore

$$^{186}Os = {}^{186}Os(s)$$

$$^{187}Os = {}^{187}Os(s) + {}^{187}Os^*$$

Where $^{187}Os^*$ is the radiogenic contribution. On the other hand,

$$\frac{d^{187}Os^*}{dt} = \lambda_{Re} \times {}^{187}Re$$

and

$$\frac{d^{187}Re}{dt} = A(t) - \lambda_{Re}{}^{187}Re$$

where $A(t)$ is the (r) process production rate for ^{187}Re.

Following Clayton[6], we can take $A(t)$ in the form of $A_0 e^{-\beta t}$. When β is large, one obtains the limiting case of sudden nucleosynthesis. When β is small one obtains a steady-state nucleosynthesis.

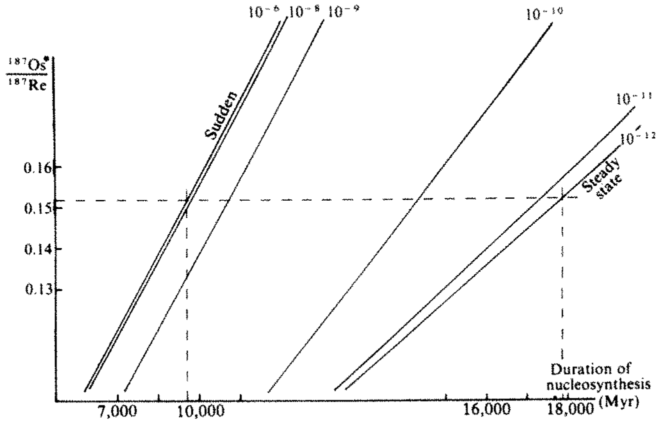

Fig. 3 Variation of the $^{187}Os^*/^{187}Re$, at the formation of the Solar System, with respect to the duration of nucleosynthesis, for different time constants (β) of the nucleosynthesis production rates.

The integration of the above differential equations give

$$\frac{^{187}Os^*}{^{187}Re} = \frac{\lambda/\beta(1-e^{-\beta\Delta t}) - (1-e^{-\lambda\Delta t})}{(e^{-\beta\Delta t} - e^{-\lambda\Delta t})} = \psi(\Delta t)$$

at the formation of the Solar System, when the solar nebula became isolated from the Galaxy. Δt is the time between starting of nucleosynthesis and meteorite formation, that is, the age of the Galaxy before the formation of the Solar System. Note that A_0 does not play any part in this equation which is a remarkable property of parent–daughter cosmochronology.

Taking as usual ^{186}Os as the reference, we obtain

$$\frac{^{187}Os^*}{^{186}Os} \Big/ \frac{^{187}Re}{^{186}Os} = \psi(\Delta t)$$

But on (s) process we know that $^{187}Os_{(s)}\sigma_{187} \sim {}^{186}Os_{(s)}\sigma_{186}$ where σ_{187} is the neutron capture cross-section of ^{187}Os.

$$\frac{^{187}Os^*}{^{186}Os} = \frac{^{187}Os}{^{186}Os_{total}} - \frac{\sigma_{186}}{\sigma_{187}} \cdot f$$

$$\frac{^{187}Re}{^{186}Os} = \left(\frac{Re}{Os}\right)_{atomic} \cdot \phi$$

where ϕ is the abundance of ^{187}Re in Re over the abundance of ^{186}Os in Os. The cross-sections (Maxwell averaged) were recently measured by Browne and Berman[23] for $kT = 30$ keV.

$$\sigma_{186}/\sigma_{187} = 0.39 \pm 0.03$$

f is a correction factor which takes into account the dependance of the cross-section on the temperature and the possible excited state of the atoms in stars. Woosley *et al.* (in ref. 7) give $f = 0.82$. The (Re/Os) ratio in carbonaceous chondrites which are supposed to represent the best estimate of the Solar System average value is 0.081 (ref. 24). The fact that this ratio does not vary too much between different meteorite classes[15,25,26], and the Earth[27] indicates that this value is probably quite constant cosmochemically speaking. From our measurements, we calculate $\phi = 40.88$, then $^{187}Re/^{186}Os = 3.20$, and $^{187}Os^*/^{187}Re = 0.152$.

Table 1 $^{187}Re/^{186}Os$ and $^{187}Os/^{186}Os$ ratio for iron meteorites and the magnetic separate from St Séverin

Sample		Sample weight (mg)	Re (p.p.m.)	Os (p.p.m.)	$^{187}Re/^{186}Os$	$^{187}Os/^{186}Os$
Iron meteorites:						
Tlacotepec (IVB)	no. 1	187.3	3.28 (3)	57.0 (4)	2.32 (3)	0.980 (4)
	no. 2	264.7	3.69 (3)	57.8 (7)	2.56 (5)	0.994 (6)
	no. 3	253.6	3.69 (3)	56.0 (6)	2.65 (5)	1.008 (6)
Canyon Diablo	IA	4075.0	0.236 (1)	2.12 (2)	4.47 (5)	1.122 (8)
Coahuila	IIA	411.9	1.40 (1)	11.11 (6)	5.06 (7)	1.187 (11)
Casas Grandes	IIIA	2446.9	0.731 (6)	9.87 (14)	2.98 (7)	1.035 (5)
Henbury	IIIA	472.0	1.53 (5)	16.9 (2)	3.63 (16)	1.080 (4)
Chondrite:						
St Séverin magnetic separate	LL6	636.8	0.939 (8)	8.00 (18)	4.72 (16)	1.164 (15)

The numbers in parentheses are the errors on the results, expressed in last digits: for example, 3.28(3) is equivalent to 3.23 ± 0.03 and 3.63(16) is equivalent to 3.63 ± 0.16.

We can then compute for these different values of (β) the curves showing the variation of $^{187}Os^*/^{187}Re$ with Δt (duration of nucleosynthesis (Fig. 3). Choosing for β the extreme values

10^{-6} yr^{-1} for sudden nucleosynthesis

10^{-12} yr^{-1} for steady state nucleosynthesis

we obtain for $^{187}Os^*/^{187}Re = 0.152$ two intercepts that give us an interval for the duration of nucleosynthesis: $8{,}700 < \Delta t < 17{,}800$ Myr and hence the age of the Galaxy is $13{,}300 < T < 22{,}400$ Myr. Note that a ±10% variation on $^{187}Os^*/^{187}Re$ would lead to a ±8% variation on T. Such an uncertainty might come from the cosmic Re/Os ratio or from the factor f or from the neutron capture cross-section ratio.

We thank G. Manhes and J. F. Minster for discussions, A. Pierre for technical assistance and P. Pellas for a magnetic separate from Saint Séverin.

Bursts of aftershocks, long-term precursors of strong earthquakes

V. I. Keilis-Borok*, L. Knopoff† & I. M. Rotvain*

* Institute of the Physics of the Earth, Academy of Sciences, Moscow, USSR
† Institute of Geophysics and Planetary Physics, University of California, Los Angeles, California 90024

Earthquakes that are followed within a short time by abnormally large numbers of aftershocks are hypothesised to be long-term precursors of stronger earthquakes. In a test of the hypothesis, 18 out of 23 strong earthquakes, in five regions worldwide, were predicted retrospectively. In comparison with a random model the precursory pattern occurs at a satisfactorily high confidence level.

THE hope that patterns of seismicity exist that are premonitory to strong earthquakes relies on the fact that the occurrence of earthquakes is controlled by the distribution of stresses and strengths within the Earth and that each earthquake in turn changes these fields. At present we cannot anticipate what such patterns should be, because the theoretical basis is inadequate. One reason for this is the absence of firmly established empirical regularities in seismicity which would provide a factual basis for theoretical studies of earthquake occurrence.

Searches for premonitory patterns of seismicity have attracted much attention, as these may possibly be established by the analysis of earthquake catalogues which are the longest record of the relevant observations. With regard to precursors of large earthquakes, there have been many purported descriptions of

0028–0836/80/030259—05$01.00

premonitory patterns of seismicity. These patterns are of three basic types—quiescence, activation and migration of epicentres. Although the results from some of these studies support the hope that premonitory patterns of seismicity exist, nevertheless, with a few exceptions, their definition is not specific enough to estimate the reliability of the pattern. To obtain such estimates one should be able to detect the pattern by a formal algorithm and to count how often it is successful as a precursor. Without such estimates of reliability, any premonitory pattern would be uncertain.

We present here an attempt to derive a formal definition of some premonitory seismicity patterns from the analysis of an earthquake catalogue, which yields a reasonable success-to-failure ratio in retrospective long-term earthquake prediction. The definition also provides constraints on the theory of earthquake occurrence.

One reason why the search for premonitory patterns of seismicity has not been successful is that aftershocks are usually disregarded as being highly predictable phenomena. The results we describe below show that, while aftershocks are indeed highly predictable, some specific traits of aftershock sequences are highly informative. These traits may represent important, descriptive aspects of the distribution and redistribution of stresses and strengths within the Earth.

Definitions

Let t be the origin time of an earthquake, λ, ϕ the longitude and latitude of its epicentre (west and south are negative), h its focal depth, and M its magnitude. The subscript j will indicate the sequence number of an earthquake in the catalogue, $t_j < t_{j-1}$.

We seek precursors of earthquakes with magnitudes $M \geqslant M_0$. These are called strong earthquakes. Our patterns will be constructed from earthquakes in the magnitude range $M_2 \equiv M_0 - \mu_2 \leqslant M \leqslant M_0 - \mu_1 \equiv M_1$ and in a time interval of duration s; the values of μ_1, μ_2 and s may be different for each of the three patterns that we will discuss.

Aftershocks are defined as follows. Consider two earthquakes with sequence numbers i and j, $j > i$. The second earthquake is an aftershock of the first if the following conditions are satisfied: the distance between their epicentres is less than $R(M_i)$; $t_j - t_i \leqslant T(M_i)$; $h_j - h_i \leqslant H(M_i)$; $M_j \leqslant M_i$. Here $T(M)$, $R(M)$ and $H(M)$ are empirical functions. If we apply this definition to an earthquake catalogue, starting with the first earthquake, we can separate the catalogue into main shocks and their aftershocks. The first earthquake of the catalogue is identified as a main shock. Each succeeding main shock can be identified after the deletion of aftershocks of the preceding main shocks. Formulas of this type have been developed[1-3] for both the worldwide and the southern California[4] catalogues for use in other aspects of the study of aftershocks and sequences or chains of interdependent earthquakes.

Pattern B (burst of aftershocks). Let $b_i(e)$ be the number of aftershocks following the ith main shock within time interval e. We consider only those main shocks with magnitudes between M_2 and M_1 and only aftershocks with magnitudes at or above some threshold $m \equiv M_0 - \mu_3$. We invoke the thresholds M_2 and m for practical reasons as all catalogues are incomplete and inhomogeneous for small magnitudes. However, these thresholds may be of some value in explaining physical relationships, as the details of premonitory patterns may be different in different magnitude ranges.

Pattern B consists of a main shock and its aftershocks for which $b_i \geqslant C$. A more flexible definition of a threshold for b_i can be given[5], but it is not required for the present purposes.

An alarm is declared for a period of τ years after pattern B is diagnosed. A strong earthquake is expected during this period, having been predicted by pattern B. The alarm is terminated either at the time a strong earthquake takes place or at the end of this period, whichever comes first.

Pattern S ('swarms') was introduced elsewhere and its parameters were adjusted to the Italian earthquake catalogue[6]. We count the number of earthquakes in a time-window from $(t-s)$ to t, in the same magnitude range as above and in a restricted depth range. Let $N(t)$ be the total number of such earthquakes in the region. A reduced number of earthquakes $n(t)$ is obtained from $N(t)$ by the elimination of aftershocks of strong earthquakes. We then consider the map of the epicentres that are counted to determine $n(t)$. From this map we determine a third function $r(t)$ which is the maximum number of epicentres that can be surrounded by a small rectangular cell of dimensions $\Delta\phi$ in latitude and $\Delta\lambda$ in longitude.

Pattern S consists of a group of earthquakes such that $n(t) > \max\{C_1, C_2\bar{N}(t)\}$ and $r(t) > C_3 n(t)$. $\bar{N}(t)$ is the average of $N(t)$ over the interval t_0 to t or from $(t-ks)$ to t. The threshold M_1 plays no part in the identification of this pattern.

Pattern Σ has been introduced elsewhere[7] and its parameters were adjusted to some of the strongest earthquakes of the world. It is represented by a peak of the function $\Sigma(t) = \sum_j G(M_j)$ where the summation takes place over the same band of time and magnitude intervals as above. Aftershocks of strong earthquakes are eliminated from the summation. $G(M)$ is specified[7]

Table 1 Score of patterns B

Regions	1 Southern California	2 N. California–Nevada (excluding Mendocino area)	3 Southern Japan	4 Northern Japan	5 New Zealand	Totals
Catalogue ref.	4, 11, 12	9	10, 14	10, 14	13	
Span of catalogue (yr)	1932–78	1945–76.5	1926–76.5	1940–76.5	1945–77	201.5
M_0	6.5	6.2	8	7.6	6.6

N_A/N_B	9/14	3/6	2/4	7/13	7/8	28/45
T_τ/T	0.37	0.28	0.10	0.27	0.53	0.30
P	96%	79%	95%	96%	95%	

N_m, total number of main shocks; N_B, number of main shocks which generate pattern B $b_i \geqslant C$, for upper value of C; N_A, number of occurrences of pattern B which are followed by strong earthquakes within τ yr; T_τ, sum of times τ before each strong earthquake, counting overlapping parts only once; T, span of the catalogue (yr); C, threshold for identification of pattern B. A variation of C within the limits indicated in the table will introduce either zero or one additional error; P, confidence level for upper value of C.

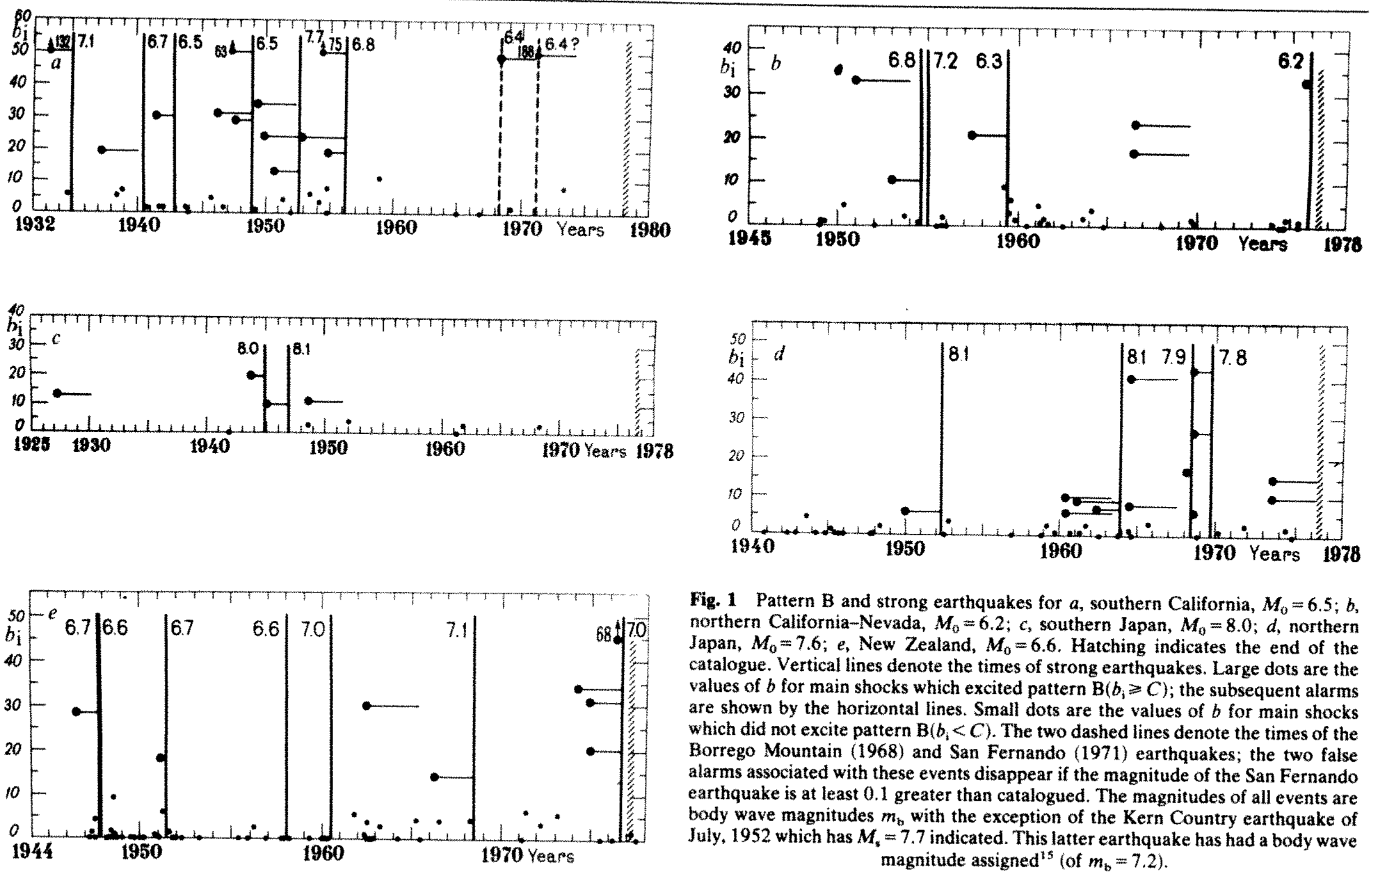

Fig. 1 Pattern B and strong earthquakes for *a*, southern California, $M_0 = 6.5$; *b*, northern California–Nevada, $M_0 = 6.2$; *c*, southern Japan, $M_0 = 8.0$; *d*, northern Japan, $M_0 = 7.6$; *e*, New Zealand, $M_0 = 6.6$. Hatching indicates the end of the catalogue. Vertical lines denote the times of strong earthquakes. Large dots are the values of *b* for main shocks which excited pattern B($b_i \geq C$); the subsequent alarms are shown by the horizontal lines. Small dots are the values of *b* for main shocks which did not excite pattern B($b_i < C$). The two dashed lines denote the times of the Borrego Mountain (1968) and San Fernando (1971) earthquakes; the two false alarms associated with these events disappear if the magnitude of the San Fernando earthquake is at least 0.1 greater than catalogued. The magnitudes of all events are body wave magnitudes m_b with the exception of the Kern Country earthquake of July, 1952 which has $M_s = 7.7$ indicated. This latter earthquake has had a body wave magnitude assigned[15] (of $m_b = 7.2$).

to be $G(M) = 10^{d(M-f)}$ where *d* and *f* are numerical parameters. Pattern Σ consists of earthquakes satisfying the condition $\Sigma(t) \geq \bar{\Sigma}$. The values $\bar{\Sigma} = cG(M_0)$, $c = 0.5$, $d = 0.91$ have been assumed elsewhere[7].

Alarms after patterns S and Σ are declared in the same manner as indicated after pattern B.

Data processing

We have tested pattern B in a retrospective 'prediction' of strong earthquakes in the five regions indicated in Table 1. Arbitrary decisions have had to be made regarding the definition of the geographical boundaries of these regions as well as the values of all parameters. No *a priori* theoretical limits can be imposed on these decisions and we have to obtain them by data fitting. This creates a danger of self-deception as the number of these decisions is rather large. To decrease this danger we have tried to make these decisions simple, uniform and, if possible, *a priori*. Also we have accepted, when possible, the arbitrary choices of parameters or thresholds made in previous studies, and we have tested the stability of our results with regard to variations in each of these choices. We have considered only those earthquakes with $h \leq 100$ km.

We have assigned the following values: $\tau = 3$ yr; $e = 2$ days; $\mu_1 = 0.1$; $\mu_2 = 1$; $\mu_3 = 3.5$. These values were obtained by data fitting for southern California[5]. To define aftershocks we took $R = 50$ km; $T(M) = 0.5$ years for $5.0 \leq M \leq 5.4$, $T(M) = 1$ yr for $5.5 \leq M \leq 6.4$ and $T(M) = 2$ yr for $M \geq 6.5$. The values of $R(M)$, $T(M)$ given elsewhere[3] for the southern California catalogue give better results, but these fine gradations are hardly warranted in view of the accuracy of some of the other catalogues used in this study. The values of $R(M)$ and $T(M)$ assumed here have the advantage that they can be used for a fast diagnosis of pattern B even before the epicentres of aftershocks are determined precisely.

The values of M_0 and *C* listed in Table 1, have been chosen separately for each region due to lack of experience and a satisfactory theory. The fact that these two parameters have been chosen *a posteriori* contributes the single largest difficulty in the evaluation of the significance of our results.

We have chosen the other parameters to be the same for all regions, even if they are unreasonably simple. This suffices for our present purpose which is to test the existence and stability of pattern B. For actual predictions, the parameters could probably be better adjusted to match the specific geophysical characteristics of the region as well as its own earthquake catalogue. More detailed studies of pattern B in some specific regions will be published elsewhere[8].

The boundaries of the southern California as well as the northern California–Nevada regions are defined elsewhere[4,9]. We straightened these boundaries slightly from the original definitions, and have deleted the area around Cape Mendocino from the northern California study as it has a distinctly isolated cluster of epicentres. The boundaries of the other regions are based on large-scale neotectonics and on the densities of epicentres.

Results

The results are summarised in Table 1. Examples of the details are documented in Table 2 and displayed in Fig. 1. The total span of all five catalogues is 202 yr. Twenty-three strong earthquakes occurred in the five regions during these time intervals. Eighteen of these earthquakes were retrospectively predicted, that is, they took place during the intervals of alarms sounded after each instance of pattern B. The total duration of these alarms is 60 yr or 30% of the total span of the catalogues. If we exclude the results for southern California, which were highly involved in the data fitting, that is, in the adjustment of parameters, we have 13 out of 17 strong earthquakes predicted for the remaining four regions; the total duration of alarms is 39 out of 155 yr or 25% of the total time.

Although these numerical values illustrate the practical efficiency of pattern B as a tool in prediction, they cannot be used in statistical tests of the existence of pattern B as, by the definition above, an alarm is terminated by the occurrence of a strong earthquake. To perform this statistical test (of the existence of pattern B), the values of the three parameters, N_A, N_B, and T_τ/T were tabulated and listed in Table 1.

The probability that a random binomial process could do as well or better than pattern B in anticipating strong earthquakes is given by the quantity $(1-P)$. This is the probability that N_A events or more will occur out of N_B tries in the fraction T_τ/T of the total catalogue time T according to a random binomial process. The values of P strongly support the hypothesis that B is a premonitory pattern, although these values of probability should only be used in a qualitative sense rather than literally. The fact that some thresholds were chosen *a posteriori* leads to an overestimation of P. On the other hand, the fact that some thresholds are chosen to be the same for all regions, leads to an underestimation of P. For example, the earthquake in southern Japan of 28 June 1948 could be deleted as a cause of a false alarm (Table 2) either by (1) changing e from 2 to 7 days, and/or (2) changing m to 5.0 from 4.5. Both of these changes are not unreasonable: in the first instance because $M_0 = 8$ is especially large and in the second because the catalogue[10] is more reliable for magnitudes greater than 5 than it is for magnitudes between 4.5 and 5. The last two false alarms for the southern California catalogue (Fig. 1) disappear if we assume that the magnitude of the San Fernando earthquake of 9 February 1971 is 6.5 instead of 6.4; this question is discussed elsewhere[5]. Similarly, the values of P could be increased by adjusting some of the parameters to take into account specific traits of the observed seismicity for each region separately. However, these adjustments would be non-unique; for the purpose of testing the existence of pattern B as a precursor, it is better to keep the criteria for all regions as uniform as possible, and that we make them, insofar as possible, *a priori*, and hence avoid tampering with the results by intuitive 'improvements' after inspection of the tabulations.

In the case of the northern California–Nevada catalogue we took $m = 3$, instead of $m = 2.7$ which would have been obtained from a literal application of our uniform definition $\mu_3 = 3.5$; this catalogue is especially inhomogeneous for $m < 3$. The errors in prediction with $m = 2.7$ and $m = 3$ are the same.

Table 2 lists the strong shocks as well as the main shocks that trigger pattern B; the strong shocks are underlined. Thus it is possible to see whether or not a strong shock was preceded by pattern B within 3 yr. Table 2 shows that our results remain essentially unaltered when the value of R is changed to 100 km and/or e to 7 d. Similar results have been obtained for the other catalogues.

We have indicated in Table 2 those events that would have been identified as aftershocks of the event immediately preceding had we used $R = 100$ km; deletion of these events from our listing would have improved our success rate as these invariably result in a reduction in N_B without a corresponding decrease in N_A. There are two examples of entries of this type in the southern California catalogue and none in the northern California and New Zealand catalogues.

A more detailed analysis of the stability of pattern B as well as the choice of the optimum parameters for the diagnosis of pattern B requires a separate study for each region. We have tried here to emphasise that pattern B can score quite satisfactory success-to-failure ratios, even with parameters that are uniform for all regions, despite the fact that each region has widely different tectonics, seismicity and quality of earthquake catalogue from the others.

Table 2 Pattern B and strong earthquakes

Values of b_i for $R = 100$ km are indicated only if they are not the same as for $R = 50$ km; δT, time from the given pattern B until the next strong earthquake; n_m, the number of all main shocks between the given and preceding strong earthquakes, or since the beginning of the catalogue in the case of the first strong earthquake; * denotes a main shock, that would have been identified as an aftershock with $R = 100$ km.

A speculation on generalisation

The same catalogues were processed to detect the presence of patterns S and Σ (Fig. 2). The value of M_0 is assumed to be the same as for pattern B. As in the papers where these patterns were introduced[6,7], the parameters were taken to be as follows: $C_1 = 0$, $C_2 = 1$, $C_3 = 0.5$, $\mu_2 = 2$, $\mu_1 = 0.5$ for Σ (absent for S), $d = 0.91$, $f = 4.5$, $s = 1$ yr for S. For Σ we varied $\bar{\Sigma}$ and s for each of the regions (Fig. 2). The absence of a pattern signifies that it could not be detected for the given region. We added data for Alaska in view of the striking success of pattern Σ.

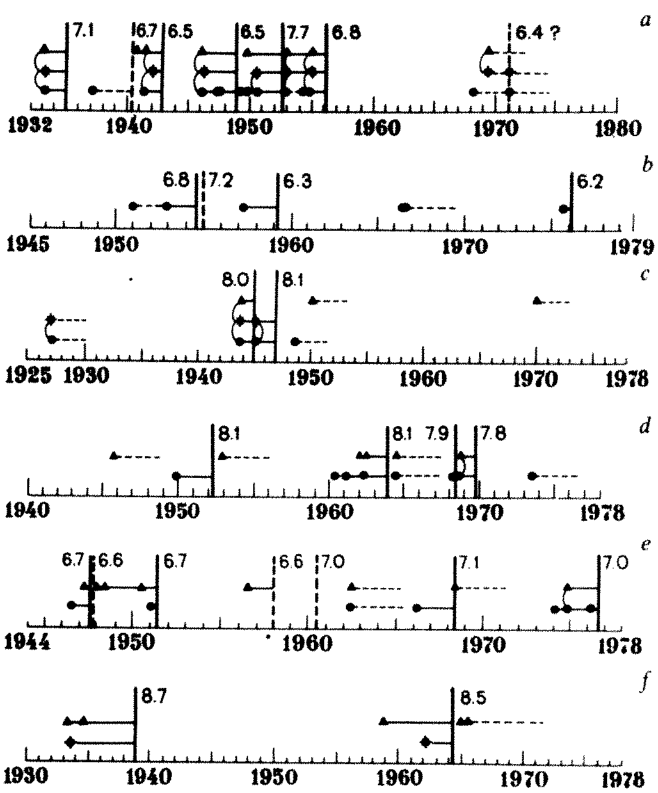

Fig. 2 Occurrence of patterns B (●), S (◆) and Σ (▲).

	$\bar{\Sigma}$	s (yr)	$\Delta\phi$	$\Delta\lambda$
a, Southern California	60	1	0.4°	0.6°
b, Northern California–Nevada				
c, Southern Japan	900	3	0.4	0.6
d, Northern Japan	700	1	1.0	1.4
e, New Zealand	95	0.5	0.4	0.6
f, Alaska	770	2	0.5	1.0

Solid horizontal line is period of alarm; dashed is false alarm. Solid vertical line is time of strong earthquake; dashed is strong earthquake not predicted by pattern B. Brackets denote different patterns generated by the same main shock and the appropriate parts of its aftershock series.

In several cases the same main shock and its aftershocks will give rise to several different patterns from among Σ, S, B. This result is not unreasonable as by definition, a main shock and its aftershocks will generate:

(1) pattern B if the number of aftershocks during the first e days is large enough;

(2) pattern S if the number of aftershocks during the time interval s, or during any part of it, is large enough; we usually take $s = 1$ yr;

(3) pattern Σ if a sufficiently large number of events have magnitudes close to the upper limit M_1.

In most cases in southern California the same main event plus its aftershocks generate two or even all three patterns. Moreover, the coincidence of a combination of two or three of the patterns eliminates false alarms without adding any failures-to-predict[5].

Patterns Σ and S also appear in conjunction before extremely strong earthquakes in the Tibet–Himalaya region[8]; in this region pattern B cannot be diagnosed, as the catalogues that are available do not include aftershocks.

We find that prediction by pattern B is successful when two conditions are satisfied: not only is a large number of aftershocks b_i required but also the main shock producing it must have a large enough magnitude; if the magnitude of a main shock is too low, but is still followed by an exceedingly large b_i, a false alarm will be generated. We have therefore introduced the threshold M_2. On the other hand we find both the numbers of false alarms and failures-to-predict increase significantly if we ignore the number of aftershocks produced by a main shock and merely consider the occurrence of a main shock itself as a possible precursor: for example, these numbers increased when we considered as a premonitor any earthquake with magnitude up to M_0, that is, by removing the gap between M_2 and M_0, by increasing M_1 and ignoring the threshold C.

We can imagine that a hypothetical generalised premonitory pattern exists which is an abnormal clustering of earthquakes in a space–time–energy domain. We call this hypothetical pattern a 'burst of seismicity'. Our three particular patterns may represent different projections of this generalised pattern. The definitions of the three are neither unique nor optimised; the use of discrete magnitude thresholds, especially in regard to large uncertainties in magnitudes of earthquakes in the catalogues, is an inadequate and troublesome aspect of the work so far. Our results indicate, however, that these patterns exist and deserve attention.

We have refrained from providing additional refinements, such as geological regionalisations or to assign probabilities to the forecasts as functions of time to the forthcoming event and its magnitude. The results of the present exploration indicate that such refinements are necessary and we hope that they would improve our success ratios, which are surprisingly high despite the simplicity of the criteria we have used.

This research was performed as part of Project III of the US–USSR cooperative programme in earthquake prediction. V.I. K.-B. was a Fairchild Scholar at the Seismological Laboratory, California Institute of Technology, and visiting professor at the Institute of Geophysics and Planetary Physics, University of California, Los Angeles. Regulation of acetylcholinesterase appearance at neuromuscular junctions *in vitro*

Lee L. Rubin*, Stephen M. Schuetze†, Cheryl L. Weill‡ & Gerald D. Fischbach

Department of Pharmacology, Harvard Medical School, 250 Longwood Avenue, Boston, Massachusetts 02115

The appearance of acetylcholinesterase (AChE) at newly formed nerve–muscle synapses depends on synaptic transmission. Synapses form when cultures are grown in the presence of acetylcholine receptor antagonists, but AChE does not accumulate at these synapses. The important component of transmission seems to be muscle activity. Treatment with dibutyryl cyclic GMP mimics muscle activity, directly inducing synaptic AChE appearance.

ACETYLCHOLINE receptors (AChRs) and acetylcholinesterase (AChE) are concentrated at adult motor endplates. The AChR is an integral membrane protein (see ref. 1 for review) restricted to the upper one-third of the postjunctional folds, whereas AChE is a peripheral protein associated with the basal lamina[2] throughout the primary and secondary synaptic clefts[3]. Even though AChRs and AChE are ultimately located at different sites, both molecules begin to accumulate within 24 h of nerve–muscle synapse formation *in vitro*[4–6] and are present in approximately equal numbers at mature junctions [3,7,8]. Therefore, one might suppose that the early AChR and AChE appearance at endplates is regulated in a coordinated way. Certain observations suggest, however, that synaptic AChRs and AChE are influenced quite differently by chronic blockade of synaptic transmission. As AChRs cluster at nerve–muscle contacts when spinal cord–muscle co-cultures are grown in the presence of α-bungarotoxin (α-BTX)[9], this process is independent of synaptic transmission. On the other hand, discrete foci of AChE fail to appear when young chick embryos are injected repeatedly with α-neurotoxin or curare[10,11]. These results have been taken as evidence that receptor antagonists block synapse formation. It is possible, however, that nerve–muscle synapses form in the presence of receptor antagonists (compare refs 12, 13) but that AChE does not accumulate in the absence of synaptic transmission. Data presented here indicate that this, in fact, is the case and, further, that activity of innervated muscle fibres is a crucial parameter regulating the early appearance of AChE at sites of transmitter release. The accumulation of AChRs and of AChE during neuromuscular junction formation is apparently not regulated in exactly the same way. A preliminary account of some of these experients has been given elsewhere[14].

As AChE accumulates rapidly at newly formed chick nerve–muscle synapses *in vitro*[6], we used this culture system to examine in more detail the influence of synaptic transmission and muscle activity on AChE. Nerve processes emerge from spinal cord explants 10 h after the fragments attach to the culture surface, and synapses form soon after nerve–muscle contact. We have shown previously that AChE can be detected histochemically at some physiologically identified sites of transmitter release within 24 h of the onset of synaptic transmission and that after 4 d of co-culture, AChE reaction product is present at the majority of functional contacts[6]. Synaptic AChE activity was also detected by measuring the time course of synaptic currents recorded with an extracellular electrode. At adult endplates, AChE serves to terminate transmitter action, and this effect is reflected in the rate of synaptic current decay[15–17]. Based on the mean time constant of synaptic current decay ($\bar{\tau}_{syn}$) recorded at 30 °C, synapses formed in culture were arbitrarily divided into three categories: fast ($\bar{\tau}_{syn} \leq 1.8$ ms), intermediate ($1.8 \text{ ms} < \bar{\tau}_{syn} < 2.6$ ms) and slow ($\bar{\tau}_{syn} \geq 2.6$ ms). Whereas 74% of the fast synapses stain for AChE, none of the slow ones stain.

Curare blocks appearance of synaptic AChE

Chick spinal cord explant–muscle co-cultures were prepared as previously described[5,6]. Thin slices cut from the brachial segments of 14-d embryonic cords were added to established muscle cultures. Curare at a final concentration of 50 µM was added to some cultures for 3–4 d beginning at the time of explant addition. Innervated myotubes in control medium twitched vigorously and were continuously active. At 50 µM, curare blocked all synaptic activity and only a few isolated contractions were observed. This high concentration of curare did not block

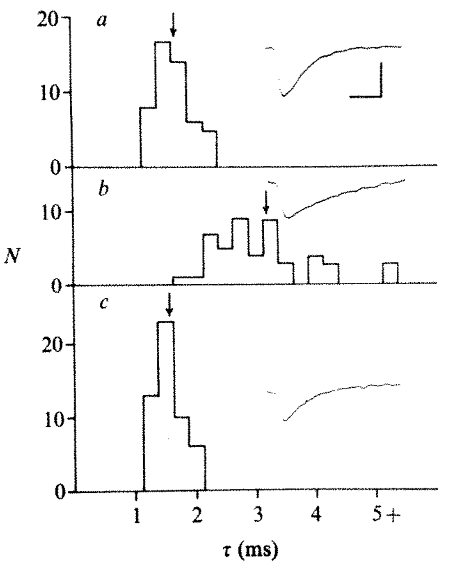

Fig. 1 Histograms of synaptic current decay time constants (τ_{syn}) recorded at 30 °C. Representative synaptic currents recorded with an extracellular microelectrode are shown as insets. Time constants were determined from exponential curves fitted to each synaptic current decay phase with an on-line computer. Arrows above each histogram indicate arithmetic means ($\bar{\tau}_{syn}$). At the control synapse (*a*), $\bar{\tau}_{syn}$ is <1.8 ms, whereas at the synapse formed and maintained in the presence of curare (50 µM for 4 d; *b*), $\bar{\tau}_{syn}$ is >2.6 ms. Both $\bar{\tau}_{syn}$ and the variance of τ_{syn} are increased at the curare-treated synapse, reflecting the lack of synaptic AChE activity[6,17]. After data in *b* were obtained, the culture was placed in control medium without curare and returned to the incubator. Two days later, *c* was obtained by recording at another synapse in the same culture. $\bar{\tau}_{syn}$ and the variance of τ_{syn} were then comparable to control. Calibration bars, 2 ms and 200 µV.

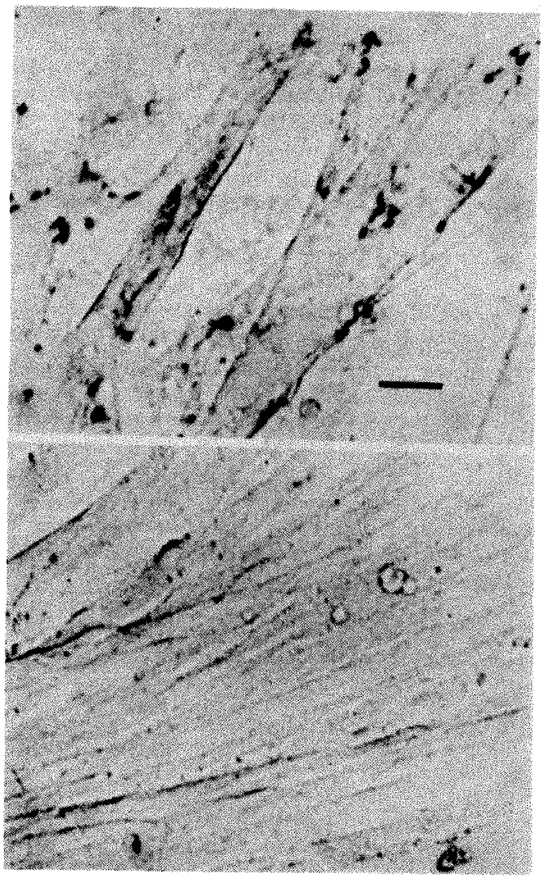

Fig. 2 Bright field view of control (upper) and 50 μM curare-treated (lower) myotubes stained for AChE according to the method of Karnovsky and Roots[32] 4 d after addition of spinal cord explants. Both fields were near (within 300 μm of) the explants. Many patches of reaction product near fine nerve processes (not visible under bright field illumination) are evident on control myotubes. Few, if any, patches are present on curare-treated myotubes. Bar, 100 μm.

the formation of synapses. Spontaneous synaptic activity was detected in most myotubes within 1–2 min of curare washout. In addition, autoradiographs of cultures treated with ^{125}I α-BTX immediately after curare washout showed that AChRs had clustered at sites of transmitter release.

Although synapses formed in the presence of curare, extracellularly recorded synaptic currents decayed relatively slowly (Fig. 1), indicating that AChE did not accumulate at sites of transmitter release. Judging from histograms of τ_{syn} constructed at 97 control and 89 curare-grown synapses (immediately after curare washout), the percentage of fast synapses decreased fivefold, whereas the percentage of intermediate synapses increased twofold and that of slow synapses threefold (Table 1). In the intermediate group, there was a shift towards higher values ($\bar{\tau}_{syn} > 2.2$ ms). The effect of curare was reversible; 1–2 d after cultures were returned to control medium, synaptic currents at most synapses decayed rapidly (Fig. 1).

Prolonged synaptic currents following curare washout were not due to an increase in the mean ACh channel open time. Estimates based on spectra of ACh-induced current fluctuations at control and curare-grown synapses were not significantly different (Table 1).

Histochemical experiments confirmed electrophysiological findings. The number of patches of AChE reaction product on myotubes near spinal cord explants in curare-grown cultures was reduced more than 10-fold compared with control (Fig. 2, Table 1). It cannot be assumed that all AChE patches are located at synapses, so sites of transmitter release were identified by extracellular recording, and then the same sites were relocated after fixation and histochemistry. Reaction product was evident at 60 of 94 control synapses, but at only 1 of 49 synapses that had formed in the presence of curare. The reversibility of the curare inhibition illustrated above was also confirmed histochemically. Many AChE patches were evident 1–2 d after return to control medium.

Curare at 50 μM did not affect the outgrowth of neurites, but in some cultures the nerve processes were more heavily stained for AChE than in control cultures. Chronic treatment with 2×10^{-8} M α-BTX also eliminated patches of AChE at synapses on innervated myotubes, but did not increase the extent of neuronal staining.

Curare blocks the appearance of 19.5S AChE

Several forms of AChE can be detected by sucrose density gradient centrifugation of extracts prepared from adult muscle (see ref. 18 for review). A high-molecular weight form sedimenting at 16S in rat[19] and 19.5S in chick[20] extracts is present in innervated but not in denervated muscle. With our method of extraction (see Fig. 3 legend), we have never detected 19.5S AChE in chick muscle cultures without added neurones or in spinal cord cultures without target myotubes, nor have we reliably detected 19.5S AChE in spinal cord explant–muscle co-cultures; the number of synapses formed may be too small. However, as shown in Fig. 3*a*, a 19.5S peak was evident in muscle cultures seeded with a large number of dissociated spinal cord cells (see ref. 21); two other peaks of AChE sedimented at 7S and 11S. In different experiments, the 19.5S peak comprised 5–10% of the total activity. In five experiments, chronic exposure to curare decreased activity in the 19.5S peak at least fourfold (Fig. 3*b*) without decreasing the total AChE-specific activity (control, 0.314±0.31 μM per min per mg; curare, 0.395±0.5 μM per min per mg). The heavy form of AChE is restricted to the endplate region of innervated rat muscle[19], but it is found in endplate-free regions of innervated chick muscle[20]. Therefore, although a useful marker for the 'innervated state', it is not clear if the 19.5S form accounts for the AChE activity at synapses detected histochemically and electrophysiologically in our cultures.

The appearance of AChE at synapses depends on muscle activity

The effect of curare and α-BTX implies that something in the sequence of events that follow ACh release—ACh binding, ACh-induced increase in membrane conductance, muscle excitation and muscle contraction—is required for the accumulation of synaptic AChE. ACh binding is probably not sufficient; synaptic AChE was drastically reduced by chronic exposure to 10 μM proadifen-HCl (SKF 525A). At this concentration, this local anaesthetic blocks ACh channels, but does not inhibit ACh binding[22]. Subthreshold synaptic conductance changes are probably not sufficient either; the appearance of AChE was substantially suppressed by tetrodotoxin, which blocks action potentials and, thus, impulse-mediated endplate potentials

Table 1 Comparison of control and curare-treated cultures

	$\bar{\tau}_{syn}$ (ms)			AChE patches	τ_0 (ms)
	1.0–1.8	1.8–2.6	>2.6	(mean ±s.e.)	(mean ±s.e.)
Control (97*)	59.8%	29.9%	10.3%	25.0±2.0 (41†)	1.34±0.08 (4‡)
Curare (89*)	12.4%	56.2%	31.5%	1.9±0.3 (58†)	1.49±0.16 (4‡)

Mean synaptic current decays ($\bar{\tau}_{syn}$) were determined at 30 °C as described in Fig. 1 legend. The number of patches of AChE reaction product (per spinal cord explant) was calculated by counting patches in the vicinity of neurites on undamaged myotubes. No more than 50 patches were counted on myotubes surrounding a single explant, so the control value is an underestimate. ACh channel open times (τ_0) were determined at fast synapses in control cultures and at slow synapses in curare-treated cultures using the technique described by Schuetze *et al.*[32].
